FastCap: A Multipole Accelerated 3-D Capacitance Extraction Program

Keith Nabors and Jacob White, Associate Member, IEEE

Abstract—In this paper a fast algorithm for computing the capacitance of a complicated 3-D geometry of ideal conductors in a uniform dielectric is described and its performance in the capacitance extractor FastCap is examined. The algorithm is an acceleration of the boundary-element technique for solving the integral equation associated with the multiconductor capacitance extraction problem. Boundary-element methods become slow when a large number of elements are used because they lead to dense matrix problems, which are typically solved with some form of Gaussian elimination. This implies that the computation grows as \( n^3 \), where \( n \) is the number of panels or tiles needed to accurately discretize the conductor surface charges. In this paper we present a generalized conjugate residual iterative algorithm with a multipole approximation to compute the iterates. This combination reduces the complexity so that accurate multiconductor capacitance calculations grow nearly as \( nm \), where \( m \) is the number of conductors. Performance comparisons on integrated circuit bus crossing problems show that for problems with as few as 12 conductors the multipole accelerated boundary element method can be nearly 500 times faster than Gaussian elimination based algorithms, and five to ten times faster than the iterative method alone, depending on required accuracy.

I. INTRODUCTION

In the design of high-performance integrated circuits and integrated circuit packaging, there are many cases where accurate estimates of the capacitances of complicated three-dimensional structures are important for determining final circuit speeds or functionality. Two examples of complicated three-dimensional structures for which capacitance strongly affects performance are dynamic memory cells and the chip carriers commonly used in high density packaging. In these problems, capacitance extraction is made tractable by assuming the conductors are ideal and are embedded in a piecewise-constant dielectric medium. Then to compute the capacitances, Laplace’s equation is solved numerically over the charge-free region, with the conductors providing boundary conditions.

Although there are a variety of numerical methods that can be used to solve Laplace’s equation, for three-dimensional capacitance calculations the usual approach is to apply a boundary-element technique to the integral form of Laplace’s equation [11], [12], [14]. In these approaches the surfaces or edges of all the conductors are broken into small panels or tiles and it is assumed that on each panel \( i \), a charge, \( q_i \), is uniformly or piecewise linearly distributed. The potential on each panel is then computed by summing the contributions to the potential from all the panels using Laplace’s equation Green’s functions. In this way, a matrix of potential coefficients, \( P \), relating the set of \( n \) panel potentials and the set of \( n \) panel charges is constructed. The resulting \( n \times n \) system of equations must be solved to compute capacitances. Typically, Gaussian elimination or Cholesky factorization is used to solve the system of equations, in which case the number of operations is order \( n^3 \). Clearly, this approach becomes computationally intractable if the number of panels exceeds several hundred, and this limits the size of the problem that can be analyzed to one with a few conductors.

An approach to reducing the computation time that is particularly effective for computing the diagonal terms of the capacitance matrix, also referred to as the self-capacitances, is to ignore small contributions to the potential coefficient matrix from pairs of panels which are separated by large distances [1]. In this paper we present a similar approach, which approximates small potential coefficients with multipole expansions. We show that this approach produces an algorithm which accurately computes both the self and coupling capacitances, and has a computational complexity of nearly \( mn \), where \( m \) is the number of conductors. Our algorithm, which is really the pasting together of three well-known algorithms [13], is presented in three sections. To begin, in the next section one of the standard integral equation approaches is briefly described, and it is shown that the algorithm requires the solution of an \( n \times n \) dense nearly symmetric matrix. Then, in Section III, a generalized conjugate residual algorithm is described and is shown to reduce the complexity of the calculation to roughly order \( mn^2 \). In Section IV, it is shown that the major computation of the conjugate residual algorithm, evaluation of a potential field from a charge distribution, can be computed in order \( n \) time using a multipole algorithm. In Section V, we describe some experimental results and in Section VI we present our conclusions. Finally, some implementation details are presented in an appendix.
II. The Integral Equation Approach

Consider a system of \( m \) ideal conductors embedded in a uniform lossless dielectric medium. For such a system, the relation between the \( m \) conductor potentials, denoted by \( \phi \in \mathbb{R}^m \), and the \( m \) total charges on each conductor, denoted by \( q \in \mathbb{R}^m \), is given by \( \bar{q} = C \phi \), where \( C \in \mathbb{R}^{m \times m} \) is referred to as the capacitance matrix. The \( j \)th column of \( C \) can be calculated by solving for the total charges on each of the conductors when the \( j \)th conductor is at unit potential and all the other conductors are at zero potential. Then the charge on conductor \( i \), \( q_i \), is equal to \( C_{ij} \).

To find the conductor charge distributions given the conductor potentials, it is necessary to solve the first-kind integral equation

\[
\phi(x) = \int_\text{surfaces} G(x, x') \sigma(x') \, da',
\]

for the surface charge density \( \sigma \), where \( x, x' \in \mathbb{R}^3 \) and are positions in three-dimensional space, \( da' \) is the incremental surface area, \( \phi \) is the potential surface potential and is known, and \( G(x, x') \) is the Green’s function, which is \( 1/\|x - x'\| \) in free space.\(^1\) Here, \( \|x - x'\| \) denotes the Euclidean distance between \( x \) and \( x' \). Given the surface charge density \( \sigma \), the total charge on the \( i \)th conductor, \( Q_i \), can be computed from

\[
Q_i = \int_{\text{ith conductor’s surface}} \sigma(x') \, da'.
\]

There are a variety of approaches for numerically computing the conductor surface charge density given the conductor potentials, some of which involve reformulating (1) as a partial differential equation and using finite difference methods in three space dimensions\(^4\), \(^6\). We will focus on the boundary-element methods applied directly to solving (1)\(^1\), \(^11\), \(^12\), \(^14\) as they have proved to be efficient and accurate when applied to problems with ideal conductors in a uniform dielectric medium. These methods are also referred to as panel methods\(^6\) or the method of moments\(^5\) in other application domains. This class of method exploits the fact that the charge is restricted to the surface of the conductors, and rather than discretizing all of free space, just the surface charge on the conductors is discretized. The surface potential, which is known, is related to the discretized surface charge through integrals of Green’s functions. The system thus constructed can then be solved for the discretized surface charge.

The simplest commonly used approach to constructing a system of equations that can be solved for the discretized surface charge is the “point-matching” or collocation method. In this method, the surfaces of \( m \) conductors in free space are discretized into a total of \( n \) two-dimensional panels (see, for example, Fig. 5(b)). For each panel \( k \), an equation is written that relates the potential at the center of that \( k \)th panel to the sum of the contributions to that potential from the charge distribution on all \( n \) panels. That is,

\[
p_k = \sum_{l=1}^n \int_{\text{panel}} \frac{\sigma_l(x')}{\|x' - x_k\|} \, da',
\]

where \( x_k \) is the center of panel \( k \), \( x' \) is the position on the surface of panel \( l \), \( p_k \) is the potential at the center of panel \( k \), and \( \sigma_l(x') \) is the surface charge density on the \( l \)th panel. The integral in (3) is the free-space Green’s function multiplied by the charge density and integrated over the surface of the \( l \)th panel. Note that as the distance between panel \( k \) and panel \( l \) becomes large compared with the surface area of panel \( l \), the integral reduces to \( q_l/\|x_k - x_l\| \), where \( x_k \) is the center of the \( l \)th panel and \( q_l \) is the total charge on panel \( l \).

In a first-order collocation method (higher order methods are rarely used), it is assumed that the surface charge density on the panel is constant\(^12\). In that case (3) can be simplified to

\[
p_k = \sum_{l=1}^n q_l \int_{\text{panel}} \frac{1}{\|x' - x_k\|} \, da',
\]

where \( a_l \) is the surface area of panel \( l \). When applied to the collection of \( n \) panels, a dense linear system results,

\[
Pq = p,
\]

where \( P \in \mathbb{R}^{n \times n} \); \( q, p \in \mathbb{R}^n \); and

\[
P_{kl} = \frac{1}{a_l} \int_{\text{panel}} \frac{1}{\|x' - x_k\|} \, da'.
\]

Note that \( q \) and \( p \) are the vectors of panel charges and potentials rather than the conductor charge and potential vectors, \( q \) and \( \phi \), mentioned above. The dense linear system of (5) can be solved, typically by some form of Gaussian elimination, to compute panel charges from a given set of panel potentials. To compute the \( j \)th column of the capacitance matrix, (5) must be solved for \( q_j \), given a \( p \) vector where \( p_k = 1 \) if panel \( k \) is on the \( j \)th conductor, and \( p_k = 0 \) otherwise. Then the \( j \)th term of the capacitance matrix is computed by summing all the panel charges on the \( j \)th conductor, that is,

\[
C_{ij} = \sum_{k \in \text{conductor}} q_k.
\]

III. Solution by the Generalized Conjugate Residual Method

In order to solve for a complete \( m \times m \) capacitance matrix, the \( n \times n \) matrix of potential coefficients, \( P \), must be factored once, usually into \( P = LU \), where \( L \) and \( U \) are strictly lower and upper triangular respectively, and this requires order \( n^2 \) operations. Then, as there are \( m \) conductors, the factored system must solved \( m \) times with \( m \) different right-hand sides, and this requires order \( mn^2 \).

\(^1\)Note that the scale factor \( 1/4\pi\varepsilon_0 \) can be ignored here and reintroduced later to give the results in units of farad.
Algorithm 1: GCR Algorithm for Solving $Py = p$
/* Setup. Note that $u_{\text{iter}}$'s are search directions and */
/* $w$ is the residual. */
/* GCR Loop. */
For $iter = 0, 1, 2, \ldots$ until converged {
    $u_{\text{iter}} = w$,
    $p_{\text{iter}} = Pw$,
    /* $\text{P-orthogonalize } p_{\text{iter}}$ with respect to $p_m$. */
    For $m = 0$ to $iter$
        $\beta = u_{\text{iter}}^T P w$,
        $u_{\text{iter}} = u_{\text{iter}} - \beta u_m$,
        $p_{\text{iter}} = p_{\text{iter}} - \beta p_m$.
    }
/* Normalize the direction. */
$p_{\text{iter}} = p_{\text{iter}} / \|p_{\text{iter}}\|$. 
$a_{\text{iter}} = u_{\text{iter}} / \|p_{\text{iter}}\|$. 
/* Update the charge and the residual. */
$q = q + \alpha a_{\text{iter}}$.
$w = w + \alpha p_{\text{iter}}$.
}

IV. ACCELERATING THE MATRIX-VECTOR PRODUCT
As can be seen from examining Algorithm 1, assuming the number of iterations required is small, the major costs of the GCR algorithm are initially forming the dense matrix $P$ and in each iteration computing the matrix-vector product $Pw$, both of which require order $n^2$ operations. Computing the capacitance matrix with Algorithm 1 is therefore at least order $mn^2$ and may be higher if the number of GCR iterations increases with the problem size. Note that if the number of panels per conductor is low, Algorithm 1 may not be much more efficient than using direct factorization.

An approach that avoids forming most of $P$, and reduces the cost of computing the matrix-vector product $Pw$, can be derived by recalling that if $w$ is thought of as representing charges distributed on panels, then $Pw$ is a potential arising from that charge distribution. In addition, if the distance between the centers of panel $i$ and panel $j$ is large compared with the panel sizes, then $P_{ij} = 1/\|x_i - x_j\|$. That is, for widely separated panels, the $j$th panel charge has the same effect on the potential at $x_i$ as would a point charge of value $w_j$ located at panel $j$’s center.

To see how these observations can help simplify the computation of $Pw$, consider the situation (depicted in 2D for simplicity) in Figs. 1 and 2. In either figure, the obvious approach to determining the potential at the $n_1$ evaluation points from the $n_2$ point charges involves $n_1 n_2$ operations; at each of the $n_1$ evaluation points one simply sums the contribution to the potential from $n_2$ charges.

An accurate approximation for the potentials for the case of Fig. 1 can be computed in many fewer operations using multipole expansions, which exploit the fact that $r >> R$ (defined in Fig. 1). That is, the details of the distribution of the charges in the inner circle of radius $R$ in Fig. 1 do not strongly affect the potentials at the evaluation points outside the outer circle of radius $r$. It is also possible to compute an accurate approximation for the potentials at the evaluation points in the inner circle of Fig. 2 in many fewer than $n_1 n_2$ operations using local expansions, which again exploit the fact that $r >> R$ (as in Fig. 2). In this second case, what can be ignored are the details of the evaluation point distribution.

A. Multipole Expansions
A rough approximation to the effect of the $n_2$ charges in the inner circle in Fig. 1 can be derived by replacing those charges with a single charge equal to their sum, placed at the inner circle’s center (see Fig. 3). The number of operations to compute the $n_1$ potentials given this simplification is then $n_2 + n_1$, $n_2$ operations to compute the sum of charges, and $n_1$ operations to calculate the potentials at the evaluation points. Note that the accuracy of this approximation improves as the separation, $r$, between the nearest evaluation point and the center of the inner circle containing the charges increases relative to the inner circle’s radius.
are called spherical harmonics [2], [8] and the $M_n^m$ are complex weights known as the multipole coefficients. The coefficients are related to the charges by

$$M_n^m = \sum_{i=1}^{n_2} q_i \rho_i^n Y_n^m(\alpha_i, \beta_i),$$  \hspace{1cm} (10)$$

where $\rho_i$, $\alpha_i$, and $\beta_i$ are the spherical coordinates of the $i$th charge relative to the sphere's center. It has been shown that the truncated multipole expansion error is bounded by

$$\left| \psi(r_j, \theta_j, \phi_j) - \sum_{n=0}^{l} \sum_{m=-n}^{n} \frac{M_n^m}{r_j^n} Y_n^m(\theta_j, \phi_j) \right| \leq K_1 \left( \frac{R}{r_j} \right)^{l+1}$$  \hspace{1cm} (11)$$

where $K_1$ is independent of $l$, and $r$ and $R$ are, as in Figs. 1 and 3, the distance to the nearest evaluation point and the radius of the sphere of charge, respectively [2]. If the nearest evaluation point is well outside the sphere, then (11) implies that all the evaluation point potentials can be accurately computed using just a few terms of the multipole expansion.

### B. Local Expansions

Multipole expansions cannot be used to simplify calculating the potentials for the evaluation points in the smaller circle of Fig. 2, since the charges are too widely distributed. However, it is still possible to compute approximate potentials at the $n_2$ charges because they are close to the circle's center. Thus the potential at an evaluation point can be approximated by

$$\sum_{i=1}^{n_1} q_i, \rho_i =$$  \hspace{1cm} (12)$$

where $\rho_i$ is the distance from the $i$th charge to the center of the circle containing the evaluation points. Estimating the potentials at the $n_2$ evaluation points therefore requires $n_2$ operations to compute the potential at the circle’s center by (12), and $n_1$ additional operations to copy that result to the $n_1$ evaluation points. Note that the approximation improves as the separation between the charges and the circle’s center increases relative to the circle’s radius.

Just as in the multipole case, it is possible to improve the accuracy of the above local expansion by including the effect of the distance between an evaluation point and the enclosing sphere’s center. In general, the truncated local expansion approximation for the exact potential in a sphere caused by charges outside the radius of the sphere is given by

$$\psi(r_j, \theta_j, \phi_j) = \sum_{n=0}^{l} \sum_{m=-n}^{n} L_n^m Y_n^m(\theta_j, \phi_j) r_j^n, \hspace{1cm} (13)$$

where $L_n^m$ are the spherical harmonics terms for the multipole coefficients.
where \( l \) is the order of the expansion, \( r_j, \theta_j, \phi_j \) are the spherical coordinates of the \( j \)th evaluation location with respect to the sphere’s center, and the \( L_m^n \) factors are the complex local expansion coefficients. For a set of \( n_2 \) charges outside the sphere, the local expansion coefficients are given by

\[
L_m^n = \sum_{i=1}^{n_2} q_i Y_m^n(\alpha_i, \beta_i),
\]

where \( q_i, \alpha_i, \) and \( \beta_i \) are the spherical coordinates of the \( i \)th charge relative to the center of the sphere containing the evaluation points. As for the multipole expansion, the error introduced by the local expansion is related to a ratio of distances,

\[
\left| \psi(r, \theta, \phi) - \sum_{n=0}^{l} \sum_{m=-n}^{n} L_m^n Y_m^n(\theta, \phi) r^n \right| < K_2 \left( \frac{R}{r} \right)^{l+1},
\]

where \( K_2 \) is independent of \( l \), and \( r \) and \( R \) are, as in Fig. 2, the distance to the nearest charge location and the radius of the sphere of evaluation points, respectively [2]. Therefore, if the charges are well outside the sphere, then the potential inside the sphere can be accurately computed using just a few terms of the local expansion.

\[C. \text{ The Multipole Algorithm}\]

Low-order multipole and local expansions can be used to accurately compute the potentials at \( n \) evaluation points arising from \( n \) panel charges in order \( n \) operations, even for general evaluation point and charge distributions, but the multipole and local expansions have to be applied carefully, both to ensure adequate separation and to avoid excess calculation. Below we give a multipole algorithm for computing the potentials at the \( n \) panel center points arising from \( n \) panel charges. The algorithm requires \( O(n) \) operations, and was originally presented in [2] with variants in [9], [13], and [17]. The algorithm is reproduced here, modified to fit the boundary-element calculations.

To begin, the smallest cube that contains the entire collection of panels for the problem of interest is determined. This cube will be referred to as the level 0, or root, cube. Then, the volume of the cube is broken into eight child cubes of equal size, referred to as level 1 cubes, and each has the level 0 cube as its parent. The panels are divided among the child cubes by associating a panel with a cube if the panel’s center point is contained in the cube. Each of the level 1 cubes is then subdivided into eight level 2 child cubes and the panels are again distributed based on their center point locations. The result is a collection of 64 level 2 cubes and a 64-way partition of the panels. This process is repeated to produce \( L \) levels of cubes and \( L \) partitions of panels starting with an eight-way partition and ending with an \( 8^L \)-way partition. The number of levels, \( L \), is chosen so that the maximum number of panels in the finest, or \( L \)th, level cube is less than some threshold (four is a typical default).

The following terms are used to concisely describe the multipole algorithm.

**Definition 1:** The evaluation points of a cube are the center points of the panels associated with the cube.

**Definition 2:** The nearest neighbors of a cube are those cubes on the same level which have a corner in common with the given cube.

**Definition 3:** The second nearest neighbors of a cube are those cubes on the same level which are not nearest neighbors but have a corner in common with a nearest neighbor.

**Definition 4:** The interaction cubes of a given cube are those cubes which are either the second nearest neighbors of the given cube’s parent, or children of the given cube’s parent’s nearest neighbors, excluding nearest or second nearest neighbors of the given cube.

There are a maximum of 189 interaction cubes for a given cube; roughly half are from a level one coarser than the level of the given cube, the rest being on the same level. The interaction cubes have two important properties. When combined with the given cube’s nearest and second nearest neighbors, they entirely cover the same volume as the given cube’s parent and the parent’s nearest and second nearest neighbors. Also, the interaction cubes are such that the distance between a point in the given cube and a point in the interaction cube is more than half the distance between the centers of the given and interaction cubes. This latter property guarantees that when multipole expansions are used to approximate the effects of interaction cubes, and when these multipole expansions are gathered together in a local expansion for the given cube, the resulting approximation will converge rapidly with increasing expansion order.

**Remark:** As the charges in this problem are not point charges, but are distributed on panels, it is necessary to ensure that each panel is entirely considered in a finest level cube in order to ensure that evaluation points in a cube are well separated from panel charges in an interaction cube. This may require breaking a panel up into several panels, but as the multipole algorithm grows linearly with the number of panels, this is not a significant computational burden.

The structure of the multipole algorithm for computing the \( n \) panel potentials from \( n \) panel charges is given below. The formulas for various transformations and shifts required are given in the Appendix. A three-letter key for each transformation is given to simplify finding the corresponding appendix formula.
Algorithm 2: Multipole Algorithm for Computing $P_w$

/*
THE DIRECT PASS: The potentials arising from nearby charges are computed directly.
*/
For each cube of the $8^i$ cubes on the finest level {
  /* Map panel charge distributions to potentials (Q2P). */
  Compute the potential at all the evaluation points in the cube arising from the charge distributions on all the panels in the cube, in the cube's nearest neighbors, and in the cube's second nearest neighbors.
}

/*
THE UPWARD PASS: Computes a multipole expansion for every cube at every level. The computation is order $n$ because the multipole expansion for any cube at a level coarser than the finest level is computed by combining the multipole expansions of its children.
*/
For each cube of the $8^i$ cubes on the finest level {
  /* Map panel charges to multipole coefficients (Q2M). */
  Construct a multipole expansion for the charge distributions on all the panels in the cube, about the cube's center.
}

For each level $i = L - 1$ to 2 {
  For each cube of the $8^i$ cubes on level $i$ {
    /* Map multipole coefficients to multipole coefficients (M2M). */
    Shift the multipole expansion about the child cube's center to a multipole expansion about the cube's center and add it to the multipole expansion for the cube.
  }
}

/*
THE DOWNWARD PASS: Computes a local expansion for every cube. The local expansion includes the effects of all panel charges not in the cube or its nearest and second nearest neighbors. Note that at the finest level this includes the effects of all panels that are not treated in the direct pass.
*/
For each level $i = 2$ to $L$ {
  For each cube of the $8^i$ cubes on level $i$ {
    /* Map local coefficients to local coefficients (L2L). */
    If the cube's parent has a local expansion, shift that expansion to a local expansion about the cube's center.
    /* Map multipole coefficients to local coefficients (M2L). */
    Convert the multipole expansion about the center of the interaction cube to a local expansion about the cube's center and add it to the local expansion for the cube.
  }
}

/*
THE EVALUATION PASS: Evaluates the local expansions at the finest level.
*/
For each cube of the $8^i$ cubes on the lowest level {
  /* Map local coefficients into potentials (L2P). */
  Evaluate the cube's local expansion for the potential at all the evaluation points in the cube, and add those computed potentials to the evaluation point potentials.
}

V. IMPLEMENTATION IN FASTCAP

Our implementation of the multipole-accelerated capacitance extraction algorithm uses an optimization which exploits the fact that the conversion and shift operations are linear functions of the charges or the expansion coefficients when the geometry is fixed. That is, the complicated evaluations involved in converting charges to potentials or multipole coefficients, shifting multipole coefficients, converting multipole coefficients to local coefficients, shifting local coefficients, converting local coefficients to potentials are all computed once and stored as matrices which operate on charges or coefficients.

As an example, consider forming a first-order multipole expansion for a collection of $k$ charges. Following (9), a first-order multipole expansion has the form

$$
\psi(r, \theta, \phi) = M_0^0 \frac{Y_0^0(\theta, \phi)}{r} + M_1^{-1} \frac{Y_1^{-1}(\theta, \phi)}{r^2} \\
+ M_1^0 \frac{Y_1^0(\theta, \phi)}{r^2} + M_1^1 \frac{Y_1^1(\theta, \phi)}{r^2},
$$

(16)

where $M_0^0, \ldots, M_1^1$ are complex multipole coefficients. Since $M_n^m$ is real for all $n$ and $M_n^{-m}$ is always the complex conjugate of $M_n^m$, the multipole expansion can be written in terms of real coefficients as

$$
\psi(r, \theta, \phi) = \overline{M}_0^0 \frac{P_0^0(\cos \theta)}{r} + \overline{M}_1^0 \frac{P_1^0(\cos \theta)}{r^2} \\
+ \overline{M}_1^1 \frac{P_1^1(\cos \theta) \cos \phi}{2r^2} + \overline{M}_1^1 \frac{P_1^1(\cos \theta) \sin \phi}{2r^2},
$$

(17)
where $M_0^0$, $M_1^1$, $M_1^1$, and $\tilde{M}_1^1$ are real coefficients and $P_n^m(\cos \theta)$ is the associated Legendre function of degree $n$ and order $m$. This equation appears as (A9) in the Appendix, where it is discussed in more detail. This low-order expansion can be more simply represented as

$$\psi(x, y, z) = \frac{1}{r} M_0^0 + \frac{1}{r^3} \tilde{M}_1^1 x - \frac{1}{r^2} \frac{y}{2r},$$

(18)

where $x$, $y$, and $z$ are the Cartesian coordinates of the evaluation points and $r = \sqrt{x^2 + y^2 + z^2}$, as usual.

The real coefficients are calculated using formulas (A11) and (A12) in the Appendix, which are analogous to (10). Writing the four equations for the four real coefficients as one matrix equation yields the $4 \times k$ linear system

$$\begin{bmatrix}
P_0^0(\cos \alpha_1) & \cdots & P_0^0(\cos \alpha_k) \\
\rho_1 P_1^1(\cos \alpha_1) & \cdots & \rho_k P_0^0(\cos \alpha_k) \\
2 \rho_1 P_1^1(\cos \alpha_1) \cos \beta_1 & \cdots & 2 \rho_k P_1^1(\cos \alpha_k) \cos \beta_k \\
2 \rho_1 P_1^1(\cos \alpha_1) \sin \beta_1 & \cdots & 2 \rho_k P_1^1(\cos \alpha_k) \sin \beta_k
\end{bmatrix}
\begin{bmatrix}
q_1 \\
q_2 \\
q_3 \\
q_4
\end{bmatrix}
= \begin{bmatrix}
M_0^0 \\
M_1^1 \\
\tilde{M}_1^1 \\
\tilde{M}_1^1
\end{bmatrix},$$

(19)

where $q_1, \ldots, q_k$ are the values of the $k$ charges. The $4 \times k$ matrix is called the Q2M conversion matrix. Its $i$th column depends only on the coordinates of the $i$th charge. Substituting for the associated Legendre functions using (A5) and (A6) from the Appendix and switching to rectangular coordinates simplifies the matrix to

$$\begin{bmatrix}
1 & \cdots & 1 \\
z_1 & \cdots & z_k \\
-2z_i & \cdots & -2z_i \\
-2z_i & \cdots & -2z_i
\end{bmatrix}
\begin{bmatrix}
q_1 \\
q_2 \\
q_3 \\
q_4
\end{bmatrix}
= \begin{bmatrix}
M_0^0 \\
M_1^1 \\
\tilde{M}_1^1 \\
\tilde{M}_1^1
\end{bmatrix}.$$

(20)

Note that the first row of the matrix implies that $M_0^0$ is the sum of all the charge strengths, making it identical to the coefficient $M_0^0$ in (16).

Since the Q2M matrix is a function of the charge positions alone, its entries need be calculated only once if several multipole algorithm potential evaluations are required for the same charge geometry. In the notation of Algorithm 2, this amounts to using the multipole algorithm to compute several $P\phi$ products with the same $P$ but with different $w$ vectors. Each time the multipole algorithm is used to form a different $P\phi$ product, a new vector of charge strengths is multiplied by the Q2M matrix, yielding a vector of updated multipole expansion coefficients. In a similar way, geometry-dependent matrices for all the other multipole algorithm conversions and shifts can be constructed and used repeatedly in subsequent $P\phi$ product calculations.

In our implementation of the complete multipole-accelerated capacitance extraction algorithm, given below, the shift and conversion coefficients are computed once and stored.

**Algorithm 3: Multipole-Accelerated Capacitance Extraction Algorithm**

/* Setup Phase. */

Divide the $m$ conductors into a total of $n$ panels.

Divide the problem domain into a hierarchy of cubes, so that each of the finest level cubes has a maximum of 4 panels.

Compute the conversion and shifting matrices from the topology.

/* Loop Through all the Conductors. */

For $j = 1$ to $m$

/* Set the Potential of the Panels on Conductor $j$ to one. */

For $k = 1$ to $n$

If panel $k$ is on conductor $j$, set $p_k = 1$.

Else $p_k = 0$.

/* Solve for the Panel Charges using MGCR. */

Use GCR (Algorithm 1) to solve $Pq = \rho$, using Multipole (Algorithm 2) to compute $P\phi$.

/* Sum the Charges on Conductor $i$ to Compute $C_{ij}$. */

For $i = 1$ to $m$ $C_{ij} = \sum_{k = \text{conductor}} q_k$.

To determine the effectiveness of this approach, the multipole accelerated algorithm was tested on the easily parameterized bus structure given in Fig. 4, for buses with $2 \times 2$ conductors through $6 \times 6$ conductors. The conductor surfaces are discretized by first cutting each conductor into sections based on where pairs of conductors overlap. In the $2 \times 2$ bus example, each conductor is cut into five sections (see Fig. 5(a)), and in the $6 \times 6$ example each conductor is divided into 13 sections. The discretization is then completed by dividing each face of each section into nine panels, as demonstrated in Fig. 5(b). The edge panels have widths that are 10% of the inner panel widths to accurately discretize the expected increased charge density near conductor edges [14].

In Table I we report the results of our experiments with the various approaches to solving (5), the matrix problem associated with the boundary element method. In the table, the total number of panels resulting from the conductor surface discretization is given, followed by the CPU times (on an IBM 6000) required to compute the entire $m \times m$ capacitance matrix, where $m$ is the number of conductors. Three methods for solving (5) are compared: direct or LU factorization, GCR, and multipole accelerated GCR (MGCR). The MGCR algorithm's CPU times are
strongly dependent on the number of expansion terms, so the time required when zero-, first-, and second-order expansions ($l = 0, 1, 2$) are used is given. Also in the table are the total number of iterations required to reduce the max norm of the residual in GCR and MGCR to 1% of its original value. The CPU times in parentheses are extrapolated. They correspond to calculations that were not possible because of the excessive memory required to store the entire potential coefficient matrix, and our lack of patience.

As is clear from the results, the multipole-accelerated GCR algorithm is very effective for the larger problems, particularly if the expansion order is low. To examine the effect of expansion order on accuracy, in Table II we compare the resulting capacitances computed by solving (5) for the $4 \times 4$ conductor problem with LU factorization, GCR, and MGCR for expansion orders 0, 1, and 2. One row of the $4 \times 4$ capacitance matrix$^2$ is given for the five different solution methods. The row chosen represents the capacitance associated with one of the conductors on the outer edge. Taking the direct method results as exact, the data indicate that MGCR can attain better than 10% accuracy in the diagonal entry of the capacitance matrix with only a zero-order ($l = 0$) expansion. To

\[ 4 \pi \varepsilon_0 = 111.27 \text{ pF/m}. \]
achieve reasonable relative accuracy in the smallest coupling capacitance, $C_{11}$, which is 50 times smaller than the diagonal entry, $C_{11}$, the second-order expansion is required. In that case MGCR produces results nearly identical to GCR, indicating that further increases in accuracy would require tightening the iterative loop tolerance as well as increasing the expansion order.

As mentioned above, computing the potentials given a new charge vector using the multipole algorithm just involves applying mapping matrices to the changing charges or multipole and local coefficients. Viewed in this way, the multipole algorithm can be compared more precisely with explicitly computing the matrix-vector product $Pw$ by counting the number of multiply-add operations required in each case. This is a way of comparing MGCR with GCR that eliminates the effects of implementation differences. The number of multiply-add operations required by the four iterative methods of Tables I and II for each $Pw$ product is plotted in Fig. 6 as a function of problem size. As seen in the plot, all the MGCR methods require fewer operations than GCR for each $Pw$ product when the number of panels, $n$, exceeds approximately 1000. Furthermore, the cost of a $Pw$ calculation grows as $n^2$ for GCR but roughly as $n$ for the MGCR methods, with the expansion order affecting only the slope.

VI. CONCLUSIONS

The above results indicate that the multipole-accelerated GCR (MGCR) algorithm is faster than both LU factorization and GCR alone for problems with more than 1000 panels. Capacitance extraction problems with nearly 6000 panels can be solved using MGCR in about 10 min on a workstation, roughly ten times faster than GCR, with comparable accuracy. Furthermore, the multipole algorithm provides an approach for trading accuracy for CPU time by reducing the expansion order; if low accuracy is tolerable, another factor of 2 speed improvement can be obtained. Finally, MGCR does not require explicit storage of the entire potential coefficient matrix, as do GCR and LU factorization, resulting in significantly smaller memory requirements. Combining these features makes it feasible to perform capacitance extraction of complicated structures as the "inner loop" of a design optimization procedure.

Additional work is under way to improve the efficiency of the multipole algorithm, and we are currently working on making the algorithm adaptive. Future research includes investigating the use of block iterative techniques to reduce the number of iterations required and extending the approach to solving problems with piecewise-constant dielectrics and ground planes. In addition, we will extend our program to handle arbitrary triangular and quadrilateral panels so that more esoteric structures can be discretized.

APPENDIX

**MULTIPOLE ALGORITHM FORMULAS**

This Appendix presents the multipole algorithm expansion, shift, and conversion formulas used in the capacitance extraction algorithm implementation. The formulas used are equivalent to those in the original multipole algorithm formulation of [2] and [3] but avoid complex arithmetic. They are obtained by combining complex conjugates in the original formulas to obtain expressions in the style of [7]. Subsection A defines the real-valued coefficients and the spherical harmonics which together are used to form the multipole formulas of subsection B.

A. Formula Components

Each multipole or local expansion term involves a coefficient multiplying a spherical harmonic. When a real coefficient expansion is used, this fact is obscured by the combination of complex conjugates. However, since the real coefficient expansions are just reorganizations of the complex coefficient formulas, the same coefficients and spherical harmonics appear in slightly different form.

---

NABORS AND WHITE: FASTCAP
1) Real-Valued Expansion Coefficients: Given a multipole or local expansion coefficient, \( G^m_n \), the corresponding real-valued coefficients are defined as

\[
\bar{G}^m_n = \begin{cases} 
2 \frac{(n + |m|)!}{(n - |m|)!} \Re \{ G^m_n \}, & |m| > 0, |m| \leq n \\
G^m_n, & m = 0, m \leq n \\
0, & \text{otherwise}
\end{cases}
\]  

(A1)

\[
G^m_n = \begin{cases} 
-2 \frac{(n + |m|)!}{(n - |m|)!} \Im \{ G^m_n \}, & m > 0, m \leq n \\
2 \frac{(n + |m|)!}{(n - |m|)!} \Im \{ G^m_n \}, & m < 0, |m| \leq n \\
0, & \text{otherwise}
\end{cases}
\]  

(A2)

All the multipole algorithm formulas are converted to real coefficients using these substitutions for the complex coefficients.

2) Spherical Harmonics: The functions

\[
Y^n_m(\theta, \phi) \doteq \frac{(n - |m|)!}{(n + |m|)!} P^{|m|}_n(\cos \theta) e^{im\phi}
\]  

(A3)

are called spherical harmonics. A spherical harmonic is part of a solution to Laplace's equation obtained by separation of variables. Here, as in [8], a spherical harmonic is the elevation (\( \theta \)) and azimuth (\( \phi \)) components of the solution. In contrast to the usual definition, however, a normalization constant is omitted following [2] and [3].

The function \( P^m_n(\cos \theta) \) is the associated Legendre function of the first kind with degree \( n \) and order \( m \). These functions are defined only when \( n \) is a nonnegative integer and \( m \) is an integer such that \(-n \leq m \leq n\). For convenience any \( P^m_n(\cos \theta) \) whose indices do not satisfy these restrictions is taken to be zero.

The recursion

\[
(n - m)P^m_n(\cos \alpha) = (2n - 1) \cos \alpha P^{m-1}_n(\cos \alpha) - (n + m - 1)P^{m-2}_n(\cos \alpha),
\]  

valid for \( 0 \leq m \leq n - 2 \), and the formulas

\[
P^m_n(\cos \alpha) = \frac{(2n)!}{2^n n!} (\sin \alpha)^n, \quad 0 \leq m
\]  

(A5)

\[
P^{m+1}_n(\cos \alpha) = (2m + 1) \cos \alpha P^m_n(\cos \alpha), \quad 0 \leq m
\]  

(A6)

can be used to recursively evaluate the Legendre functions [7], [10].

B. Real Coefficient Multipole Algorithm Formulas

Using the real-valued coefficients and the spherical harmonics of the previous section, the multipole algorithm formulas used in the capacitance extraction algorithm are obtained. The resulting real coefficient formulas eliminate the need for complex arithmetic and square root calculations.

1) Multipole Expansion (Q2M, M2P): The order \( l \) multipole expansion approximation to the potential, \( \psi \), at the point \((r, \theta, \phi)\) is

\[
\psi(r, \theta, \phi) = \sum_{n=0}^{I} \sum_{m=-n}^{n} \frac{M^m_n}{r^{n+1}} Y^n_m(\theta, \phi). \]  

(A7)

Applying the definition of the spherical harmonic, \( Y^n_m \), gives

\[
\psi(r, \theta, \phi) = \sum_{n=0}^{I} \sum_{m=-n}^{n} \frac{M^m_n}{r^{n+1}} \frac{(n - |m|)!}{(n + |m|)!} \cdot P^{|m|}_n(\cos \theta)e^{im\phi}. \]  

(A8)

Substituting the real coefficients using (A1) and (A2) yields the real coefficient multipole expansion.

\[
\psi(r, \theta, \phi) = \sum_{n=0}^{I} \sum_{m=-n}^{n} \frac{1}{r^{n+1}} \sum_{m=-n}^{n} \frac{(n - |m|)!}{(n + |m|)!} \cdot P^{|m|}_n(\cos \theta) (\tilde{M}^m_n \cos(m\phi) + \tilde{M}^m_n \sin(m\phi)). \]  

(A9)

The complex coefficient local expansion conversion is nearly identical.

A multipole expansion is constructed from \( k \) charges with strengths \( q_i \) and positions \((\rho_i, \alpha_i, \beta_i)\), \( i = 1, \cdots, k \), using

\[
M^m_n \doteq \sum_{i=1}^{k} q_i \rho_i^n Y^{-m}_n(\alpha_i, \beta_i). \]  

(A10)

Substituting (A1) and (A2) gives expressions for the real multipole coefficients corresponding to a set of \( k \) charges:

\[
\bar{M}^m_n = \begin{cases} 
2 \sum_{i=1}^{k} q_i \rho_i^n P^{|m|}_n(\cos \alpha_i) \cos(m\beta_i), & |m| > 0, |m| \leq n \\
\sum_{i=1}^{k} q_i \rho_i^n P^0_n(\cos \alpha_i), & m = 0, m \leq n \\
0, & \text{otherwise}
\end{cases}
\]  

(A11)

\[
\tilde{M}^m_n = \begin{cases} 
2 \sum_{i=1}^{k} q_i \rho_i^n P^{|m|}_n(\cos \alpha_i) \sin(m\beta_i), & |m| > 0, |m| \leq n \\
0, & \text{otherwise}
\end{cases}
\]  

(A12)
2) Local Expansion (Q2L, L2P): The order \( l \) local expansion approximation to the potential \( \psi \), at the point \((r, \theta, \phi)\) is

\[
\psi(r, \theta, \phi) = \sum_{n=0}^{l} \sum_{m=-n}^{n} \mathcal{L}_n^m \mathcal{P}_n^m(\theta) r^n.
\]

or

\[
\psi(r, \theta, \phi) = \sum_{n=0}^{l} \sum_{m=-n}^{n} \frac{(n-m)!}{(n+m)!} \cdot \mathcal{L}_n^m \mathcal{P}_n^m(\theta) r^n.
\]

Substituting the real coefficients using (A1) and (A2) yields the real coefficient local expansion:

\[
\psi(r, \theta, \phi) = \sum_{n=0}^{l} \sum_{m=-n}^{n} \frac{(n-m)!}{(n+m)!} \cdot \mathcal{L}_n^m \cos(\theta) e^{im\phi} r^n.
\]

A local expansion is constructed from \( k \) charges with strengths \( q_i \) and positions \((p_i, \alpha_i, \beta_i)\), \( i = 1, \ldots, k \), using

\[
\mathcal{L}_n^m = \sum_{i=1}^{k} \frac{q_i}{\rho_i^{n+1}} Y_n^m(\alpha_i, \beta_i).
\]

Substituting (A1) and (A2) gives expressions for the real multipole coefficients corresponding to a set of charges:

\[
\mathcal{L}_n^m = \begin{cases} \frac{2}{\rho_{n+1}^{m+1}} \mathcal{P}_n^m(\cos \alpha) \cos(m\beta), & |m| > 0, |m| \leq n \\ \sum_{i=1}^{k} \frac{q_i}{\rho_i^{n+1}} \mathcal{P}_n^m(\cos \alpha), & m = 0, m = n \\ 0, & \text{otherwise} \end{cases}
\]

\[
\mathcal{L}_n^m = \begin{cases} \frac{2}{\rho_{n+1}^{m+1}} \mathcal{P}_n^m(\cos \alpha) \sin(m\beta), & |m| > 0, |m| \leq n \\ 0, & \text{otherwise}. \end{cases}
\]

3) Multipole Expansion Shift (M2M): Consider a multipole expansion about the point \((\rho, \alpha, \beta)\). The potential at a given point results when its coordinates relative to \((\rho, \alpha, \beta)\) are substituted into the expansion. If the expansion about \((\rho, \alpha, \beta)\) has coefficients \( \mathcal{O}_n^m \), then the coefficients of a shifted multipole expansion about the origin, \( \mathcal{N}_n^m \), are given by

\[
\mathcal{N}_n^m = \sum_{n=0}^{l} \sum_{m=-n}^{n} \frac{j+k}{(j-k)!} \frac{j}{(j-n-k+m)!} \frac{j}{(j-n+k-m)!} \mathcal{O}_j^m \mathcal{P}_n^m(\cos \alpha) \mathcal{P}_n^m(\cos \beta) r^n.
\]

Substituting for the spherical harmonics using (A3) and for the complex coefficients with (A1) and (A2) gives the real coefficient multipole expansion shift formulas for \( j \geq k \geq 0 \):

\[
\mathcal{N}_n^m = \sum_{n=0}^{l} \sum_{m=-n}^{n} \frac{j+k}{(j-k)!} \frac{j}{(j-n-k+m)!} \frac{j}{(j-n+k-m)!} \mathcal{O}_j^m \mathcal{P}_n^m(\cos \alpha) \mathcal{P}_n^m(\cos \beta) r^n.
\]
expansion about the origin, with coefficients $N_j^f$, using

$$N_j^f = \sum_{n=0}^{j} \sum_{m=-n}^{n} \frac{\sqrt{(j+n+m-k)! (j+n-m+k)!}}{\sqrt{(n+m)!(n-m)!}} i^{j-m} y_{n-m}^{m-n} (\alpha, \beta) O_n^m \rho^{j-n}. \quad (A23)$$

Substituting for the spherical harmonics using (A3) and for the complex coefficients with (A1) and (A2) gives the real coefficient multipole to local expansion conversion formulas for $l \geq j \geq k \geq 0$:

$$\overline{N}_j^f = \frac{f_l(k)}{\rho^j (j-k)!} \sum_{n=0}^{l} (-1)^n \sum_{m=0}^{n} \frac{P_{j+n}^{m-k} (\cos \alpha) (j+n-|m-k|)!}{(n+m)!} i^{j-m-n-k}$$

- $\{ \overline{O}_n^m \cos [(m-k) \beta] + \overline{O}_n^m \sin [(m-k) \beta] \}$

+ $P_{j+n}^{m-k} (\cos \alpha) (j+n-m-k)! (n+m)!$

- $\{ \overline{O}_n^m \sin [(m-k) \beta] + \overline{O}_n^m \cos [(m-k) \beta] \}$

$$= \frac{1}{\rho^j (j-k)!} \sum_{n=0}^{l} (-1)^n \sum_{m=0}^{n} P_{j+n}^{m-k} (\cos \alpha) (j+n-|m-k|)! \frac{i^{j-m-n-k}}{(n+m)!}$$

- $\{ \overline{O}_n^m \sin [(m-k) \beta] + \overline{O}_n^m \cos [(m-k) \beta] \}$

+ $P_{j+n}^{m-k} (\cos \alpha) (j+n-m-k)! (n+m)!$

- $\{ \overline{O}_n^m \sin [(m-k) \beta] - \overline{O}_n^m \cos [(m-k) \beta] \}$. \quad (A24)

Here

$$f_l(k) = \begin{cases} 1, & k \neq 0 \\ 1/2, & k = 0. \end{cases} \quad (A26)$$

5) Local Expansion Shift (L2L): An order $l$ local expansion about the point $(\rho, \alpha, \beta)$, with coefficients $O_n^m$, can be converted to an order $l$ local expansion about the origin, with coefficients $N_j^f$, using

$$N_j^f = \sum_{n=j}^{l} \sum_{m=-n}^{n} \frac{\sqrt{(n+m)!(n-m)!}}{\sqrt{(n-j+m-k)!(n-j-m+k)!(j+k)!(j-k)!(-1)^j}} \rho^j y_{n-j}^{m-j} (\alpha, \beta) O_n^m \rho^n. \quad (A27)$$

Substituting for the spherical harmonics using (A3) and for the complex coefficients with (A1) and (A2) gives the real coefficient local expansion shift formulas for $j \geq k \geq 0$:

$$\overline{N}_j^f = \frac{f_l(k)}{\rho^j (j-k)!} \sum_{n=0}^{j} (-1)^n \sum_{m=0}^{n} \frac{P_{n-j}^{m-k} (\cos \alpha) i^{j-m-n-k}}{(n-j+|m-k|)! (n-m)!}$$

- $\{ \overline{O}_n^m \cos [(m-k) \beta] + \overline{O}_n^m \sin [(m-k) \beta] \}$

+ $P_{n-j}^{m-k} (\cos \alpha) (n-j+m+k)! (n-m)!$

- $\{ \overline{O}_n^m \sin [(m-k) \beta] + \overline{O}_n^m \cos [(m-k) \beta] \}$

- $\{ \overline{O}_n^m \sin [(m-k) \beta] - \overline{O}_n^m \cos [(m-k) \beta] \}$. \quad (A28)

The function $f_l(k)$ is given by (A26).

**ACKNOWLEDGMENT**

The authors would like to thank D. Ling and A. Ruehli of the I.B.M. T. J. Watson Research Center for many discussions and for their help in understanding the integral equation method, and A. Ruehli for a suggestion that led to the approach presented here. In addition, the authors would like to acknowledge the helpful discussions with T. Simon and the members of the M.I.T. custom integrated circuits group.
