

Stochastic Networked Control Systems with Dynamic Protocols[†]

Duarte Antunes, João P. Hespanha, and Carlos Silvestre

ABSTRACT

We consider networked control systems in which sensors, controllers, and actuators communicate through a shared network that introduces stochastic intervals between transmissions, delays and packet drops. Access to the communication medium is mediated by a protocol that determines which node (one of the sensors, one of the actuators, or the controller) is allowed to transmit a message at each sampling/actuator-update time. We provide conditions for mean exponential stability of the networked closed loop in terms of matrix inequalities, both for investigating the stability of given protocols, such as static round-robin protocols and dynamic maximum error first-try once discard protocols, and to design new dynamic protocols. The main result entailed by these conditions is that if the networked closed loop is stable for a static protocol then we can provide a dynamic protocol for which the networked closed loop is also stable. The stability conditions also allow for obtaining an observer-protocol pair that reconstructs the state of an LTI plant in a mean exponential sense and less conservative stability results than other conditions that previously appeared in the literature.

Key Words: Networked Control Systems, Dynamic Protocols, Scheduling, Stochastic Systems

I. Introduction

The proliferation of network communication systems in recent years paved the way for important research in the area of networked control systems. This research area addresses control loops closed via a shared network that provides the medium for sensor, actuator and controller nodes to communicate.

Walsh and co-authors [1] made strides in the analysis of control systems closed via a local area

network, such as the controller-area network, the ethernet and wireless 802.11 networks. The key assumptions in [1] are that there exists a bound on the interval between transmissions denoted by *maximum allowable transfer interval* (MATI), and that transmission delays and packet drops are negligible. In [1] an emulation set-up is considered in the sense that the controller for the networked control system is obtained from a previously designed stabilizing continuous-time controller. Two basic types of protocols have been proposed: static protocols, such as the round-robin (RR) protocol where nodes take turns transmitting data in a periodic fashion; and dynamic protocols such as the maximum error first-try once discard (MEF-TOD) protocol, where the node that has the top priority in using the communication medium is the one whose current value to transmit differs the most from the last transmitted value. Under this setup, one can attempt to provide an upper bound on the MATI for which stability can be guaranteed. Since these protocols have been proposed in the papers referenced above, MATI bounds have been

improved [2], [3], [4]. Although, [1] illustrate through simulations that using the MEF-TOD protocol allows for preserving stability of the networked closed loop for a larger MATI than that obtained when using the RR protocol, and similar conclusions are obtained in [2]-[4] from sufficient stability conditions, no analytical result has been established proving that this holds in general.

As mentioned in [1], the occurrence of transmission events on the network is often more appropriately modeled as a random process. This feature is taken into account in [5], which considers networked control systems with MEF-TOD and RR protocols, and independent and identically distributed (i.i.d.) intervals between transmissions. It is shown that stability can be guaranteed for distributions of the inter-transmission intervals that have a support larger than previously derived deterministic upper bounds for the MATI [1], [2], [3]. The conservativeness of these results for linear networked control systems using the RR protocol was eliminated in [6]. Recently, [7] addresses a model of networked control systems with i.i.d. intervals between transmissions and stochastic delays for a class of quadratic protocols that is more general than MEF-TOD. Through a convex over-approximation approach, sufficient conditions are given for mean exponential stability. In [8] a method is proposed to design an observer-protocol pair to asymptotically reconstruct the states of an LTI plant where the plant outputs are sent through a network with constant intervals between transmissions. The protocol to be designed can be viewed as a weighted version of the MEF-TOD.

In the present paper we follow this line of research considering that the network imposes i.i.d. intervals between transmissions. We also take into account stochastic delays modeled as in [7], and packet drops. We consider that access to the network is mediated by a dynamic protocol specified as follows. Associated to each node there is a set of quadratic state functions, which are evaluated at a given transmission time. The node allotted to transmit is the one corresponding to the least value of these quadratic state functions. These protocols are more general than quadratic protocols considered in [7] and thus more general than the MEF-TOD protocol.

We establish two stability results for the networked control system, both providing conditions in terms of linear matrix inequalities (LMIs) for investigating the stability in a mean exponential sense of given protocols, and conditions in terms of BMIs to design quadratic state functions, specifying the dynamic protocol, that yield the networked closed loop stable. The first stability result allows to prove that if the networked

closed loop is stable for a static protocol then we can provide a dynamic protocol for which the networked closed loop is also stable. This is the main contribution of the paper and gives an analytical justification on why one should utilize dynamic protocols rather than static, while, e.g., in [1], this conclusion is only illustrated through simulation. The second stability result allows us to extend the work [8] to the case where transmission intervals are stochastic. We also address the relation of this stability result with the necessity of existence of a quadratic stochastic Lyapunov function that assures stability for the networked control system.

We illustrate through benchmark examples, that the conditions in this paper are significantly less conservative than other conditions that previously appeared in the literature.

A preliminary version of the results presented here appeared in the conference paper [9]. Besides including all the formal proofs of the results, here we establish the connection between the second of our two main stability results and the existence of a quadratic stochastic Lyapunov function that assures stability for the networked control system.

The remainder of the paper is organized as follows. The networked control problem set up is given in Section II. The main results are stated in Section III. In Section IV we compare our results with previous works. Concluding remarks are given in Section V. The proofs of the results are provided in the appendix.

Notation We denote by I_n and O_n the $n \times n$ identity and zero matrices, respectively, and by $\text{diag}([A_1 \dots A_n])$ a block diagonal matrix with blocks A_i . For dimensionally compatible matrices A and B , we define $(A, B) := [A^T \ B^T]^T$.

II. PROBLEM FORMULATION

We start by introducing the networked control stability problem and then we show that it can be casted into analyzing the stability of an impulsive system.

2.1. Networked Control Set-up

We consider a networked control system for which sensors, actuators, and a controller, are connected through a communication network, possibly shared with other users. The plant and controller are described by the following state-space model:

$$\text{Plant: } \dot{x}_P = A_P x_P + B_P \hat{u}, \quad y = C_P x_P \quad (1)$$

$$\text{Controller: } \dot{x}_C = A_C x_C + B_C \hat{y}, \quad u = C_C x_C + D_C \hat{y}. \quad (2)$$

Following an emulation approach, we assume that the controller has been designed to stabilize the closed loop, when the process and the controller are directly connected, i.e., $\hat{u}(t) = u(t)$, $\hat{y}(t) = y(t)$, $t \geq 0$ and we are interested in analyzing the effects of the network on the stability of the closed loop. We denote the times at which a node transmits a message by $\{t_k, k \in \mathbb{N}\}$, and assume that \hat{u} and \hat{y} are held constant between transmission times, i.e.,

$$\hat{u}(t) = \hat{u}(t_k), \quad \hat{y}(t) = \hat{y}(t_k), \quad t \in [t_k, t_{k+1}), \quad k \in \mathbb{Z}_{\geq 0}. \quad (3)$$

We denote by e the error signal between process output and controller input ($\hat{y} - y$) and between controller output and process input ($\hat{u} - u$). In particular,

$$e := (\hat{y} - y, \hat{u} - u). \quad (4)$$

We assume that while m nodes compete for the network, only one of them is allowed to transmit at each given transmission time. However, in our terminology a single transmitting node could be associated with several entries of the process output y or with several entries of the controller output u . For simplicity, we assume that the sensors and actuators have been ordered in such a way that we can partition the error vector as $e = (e_1, \dots, e_m)$, where each $e_i(t) \in \mathbb{R}^{s_i}$ is the error associated with node $i \in \mathcal{M} := \{1, \dots, m\}$. The state of the networked control system is thus defined by the vector $x := (x_P, x_C, e)$, where $x_P \in \mathbb{R}^{n_P}$, $x_C \in \mathbb{R}^{n_C}$, $e \in \mathbb{R}^{n_e}$, and $x \in \mathbb{R}^{n_x}$. We are interested in scenarios for which the following assumptions hold:

- (i) The time intervals $\{h_k := t_{k+1} - t_k\}$ are i.i.d. described by a probability measure μ with support on $[0, \gamma]$, $\gamma \in \mathbb{R}_{\geq 0} \cup \{+\infty\}$, i.e., $\text{Prob}(a \leq h_k \leq b) = \int_a^b \mu(dr)$ for $a, b \in [0, \gamma]$.
- (ii) Corresponding to a transmission at time t_k there is a transmission delay d_k no greater than $h_k = t_{k+1} - t_k$; A joint stationary probability density χ describes (h_k, d_k) , in the sense that

$$\text{Prob}(a \leq h_k \leq b, c \leq d_k \leq d) = \int_a^b \int_c^d \chi(dr, ds) \quad (5)$$

where $a, b \in [0, \gamma]$ and $\text{Prob}(a \leq h_k \leq b, c \leq d_k \leq d) = 0$ if $c > b$. In view of (i) and (ii), we have that $\mu([a, b]) = \chi([a, b], [0, b])$.

- (iii) At each transmission time there is a probability p_{drop} that a packet may not arrive at its destination or that it may arrive corrupted (packet drop).
- (iv) The nodes implement one of the two protocols:
Dynamic protocol (DP): This protocol is specified

by m_D symmetric matrices $\{R_i, i \in \mathcal{M}_D\}$, $\mathcal{M}_D := \{1, \dots, m_D\}$, $m_D \geq m$. A subset of these matrices $\{R_i, i \in I_j\}$ is associated with node $j \in \mathcal{M}$ where $I_j := \{i_1^j, i_2^j, \dots, i_{r_j}^j\}$ is an index subset of \mathcal{M}_D . These subsets are assumed to be nonempty, i.e., $r_j \geq 1$, disjoint, and the r_j are such that $\sum_{j=1}^m r_j = m_D$. The node j allotted to transmit at t_k is determined by the map $d : \mathbb{R}^{n_x} \mapsto \mathcal{M}$,

$$d(x(t_k^-)) = d_1 \circ d_2(x(t_k^-)), \quad (6)$$

where $d_2 : \mathbb{R}^{n_x} \mapsto \mathcal{M}_D$ is given by

$$d_2(x(t_k^-)) := \text{argmin}_{i \in \mathcal{M}_D} x(t_k^-)^\top R_i x(t_k^-), \quad (7)$$

and $d_1 : \mathcal{M}_D \mapsto \mathcal{M}$ is given by

$$d_1(i) := \{j : i \in I_j\}. \quad (8)$$

In case the minimum in (7) is achieved simultaneously for several values of the index i , stability of the networked control system should be guaranteed regardless of the specific choice for the argmin. In view of (6), the error e is updated at time t_k according to

$$e(t_k) = (I_{n_e} - \Lambda_{d(x(t_k^-))})e(t_k^-), \quad (9)$$

where $\Lambda_j := \text{diag}([0_{\sum_{i=1}^{j-1} s_i} I_{s_j} 0_{\sum_{i=j+1}^m s_i}])$, $j \in \mathcal{M}$. That is, only the components of \hat{y} or \hat{u} associated with the node that transmits are updated by the corresponding components of $y(t_k^-)$ or $u(t_k^-)$. We call a dynamic protocol *regular* if for every $j \in \mathcal{M}_D$ there exists a state x such that j is the unique index such that $j = \text{argmin}_{i \in \mathcal{M}_D} x^\top R_i x$. A non regular dynamic protocol can always be made regular by discarding unnecessary matrices R_i .

Static Protocol (SP): The nodes transmit in a m_S -periodic sequence determined by a periodic function

$$s : \mathbb{N} \mapsto \mathcal{M} \quad (10)$$

with period m_S . In this case, the error e is updated at time t_k according to

$$e(t_k) = (I_{n_e} - \Lambda_{s(k)})e(t_k^-). \quad (11)$$

We assume that s is onto, i.e., each node transmits at least once in a period. When $m_S = m$, each node transmits exactly once in a period.

As mentioned in Section I, Assumptions (i)-(iii) are appropriate for networked control systems in which feedback loops are closed via local area networks

(cf. [1], [10]). In particular, Assumption (i) holds for scenarios in which nodes attempt to do periodic transmissions of data, but these regular transmissions may be perturbed by the medium access. It is typically the case in Carrier Sense Multiple access (CSMA) protocols that nodes may be forced to back-off for a typically random amount of time until the network becomes available. Note that networks with CSMA protocols protocol, such as the Ethernet of the Wireless 802.11 are prevalent in nowadays communication systems. The probability distribution of the time interval between transmissions, which can be estimated experimentally or by running Monte Carlo simulations of the protocol, is determined by two factors: the congestion of the network and the delay introduced by the medium access protocol.

The class of dynamic protocols that we describe in (iv) allow a node to transmit if the state of the networked control system lies on a given region of the state space, partitioned according to quadratic restrictions. This class of protocols boils down to the quadratic protocols introduced in [7] when $m_D = m$. Thus, our definition allows for ampler partitions of the state-space than quadratic protocols, and as we shall see it also allows to obtain that dynamic protocols are in a sense better than static ones. If we make $m_D = m$ and choose $P > 0$ such that $R_i = P - \text{diag}([0_{n_P+n_C} \Lambda_i]) > 0$, then (6) becomes the usual MEF-TOD protocol, where the node that transmits is the one with the maximum norm of the error $e_i(t)$ between its current value and its last transmitted value.

2.2. Impulsive systems

Suppose that there are no delays, i.e. $d_k = 0$, and no packet drops, i.e., $p_{\text{drop}} = 0$. Then we can write the networked control system (1), (2), (3), (4), in the form of the following impulsive system

$$\begin{aligned} \dot{x}(t) &= Ax(t), \quad t \in \mathbb{R}_{\geq 0}, t \neq t_k \\ x(t_k) &= J_{\text{p}(x(t_k^-), k)} x(t_k^-), \quad k \in \mathbb{N}_0 \end{aligned} \quad (12)$$

where $x \in \mathbb{R}^{n_x}$, $x(0^-) := x_0$, and $t_{k+1} - t_k$ are i.i.d. random variables characterized by the probability density μ , and the map p takes the following form for dynamic and static protocols

$$\text{DP:} \quad \text{p}(x(t_k^-), k) = \text{d}(x(t_k^-)) \quad (13)$$

$$\text{SP:} \quad \text{p}(x(t_k^-), k) = \text{s}(k). \quad (14)$$

For example, the following expressions for A and $\{J_i, i \in \mathcal{M}\}$, correspond to the case in which the

controller and plant are directly connected and only the outputs are transmitted through the network, i.e., $\hat{u}(t) = u(t)$, $x = (x_P, x_C, \hat{y} - y)$.

$$\begin{aligned} A &= \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} \\ A_{11} &= \begin{bmatrix} A_P + B_P D_C C_P & B_P C_C \\ B_C C_P & A_C \end{bmatrix} \\ A_{12} &= \begin{bmatrix} B_P D_C \\ B_C \end{bmatrix} \\ A_{21} &= -[C_P \quad 0] A_{11} \\ A_{22} &= -[C_P \quad 0] A_{12} \\ J_i &= \text{diag}([I_{n_P+n_C} \quad I_{n_e} - \Lambda_i]), \quad i \in \mathcal{M}. \end{aligned} \quad (15)$$

This case will be considered in Section IV. Expressions for the general case considered in Section II can be easily obtained (see, e.g., [11, p. 5]).

To take into account delays and packet drops modeled as described in Section II, we consider the following impulsive system

$$\begin{aligned} \dot{x}(t) &= Ax(t), \quad t \in \mathbb{R}_{\geq 0}, \quad t \neq t_k \\ x(t_k) &= K_{\text{p}(x(t_k^-), k)}^{q_k} x(t_k^-), \quad k \in \mathbb{N}_0 \\ x(s_k) &= Lx(s_k^-), \quad t_k \leq s_k \leq t_{k+1}, \end{aligned} \quad (16)$$

where $\text{p}(x_k, k)$ is defined as in (13) for dynamic protocols and as in (14) for static protocols, and the initial condition is set to $x(0^-) := x_0$. The random variables t_k and s_k are completely defined by the inter-sampling times $h_k := t_{k+1} - t_k$ and by the delays $d_k := s_k - t_k$. The (h_k, d_k) are i.i.d., and are as described by (5). The $q_k \in \{1, \dots, n_q\}$ are i.i.d., and such that $\text{Prob}[q_k = j] = w_j \quad \forall j \in \{1, \dots, n_q\}, k \geq 0$. We provide below expressions for A , L , w_i and K_i^j , $i \in \mathcal{M}, j \in \{1, \dots, n_q\}$ which model the case where the controller and the plant are directly connected and only the plant outputs are transmitted through the network, i.e., $\hat{u}(t) = u(t)$. The state is now considered to be $x = (x_P, x_C, \hat{y}, v) \in \mathbb{R}^{n_x}$ where $v \in \mathbb{R}^{n_e}$ is an auxiliary vector (v_1, \dots, v_m) that is updated with the sampled value $v_j = y_j(t_k)$ at each sampling time t_k at which node j is allowed to transmit. However, the update only takes place if a packet sent at t_k is not dropped and the sampled value v_j is only used to update the value of \hat{y}_j after a transmission delay d_k , at the time $s_k = t_k + d_k$.

$$\begin{aligned}
A &= \begin{bmatrix} A_{11} & A_{12} & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \\
A_{11} &= \begin{bmatrix} A_P & B_P C_C \\ 0 & A_C \end{bmatrix} \\
A_{12} &= \begin{bmatrix} B_P D_C \\ B_C \end{bmatrix} \\
n_q &= 2, w_1 = 1 - p_{\text{drop}}, w_2 = p_{\text{drop}} \\
K_i^1 &= \begin{bmatrix} I_{n_P} & 0 & 0 & 0 \\ 0 & I_{n_C} & 0 & 0 \\ 0 & 0 & I_{n_e} & 0 \\ \Lambda_i C_P & 0 & 0 & I_{n_e} - \Lambda_i \end{bmatrix}, \\
K_i^2 &= I_{n_P + n_C + 2n_e}, i \in \mathcal{M} \\
L &= \begin{bmatrix} I_{n_P + n_C} & 0 & 0 \\ 0 & 0 & I_{n_e} \\ 0 & 0 & I_{n_e} \end{bmatrix}.
\end{aligned} \tag{17}$$

Again, the expressions for the general case considered in Section II can be easily obtained. It is also important to mention that there are other ways to model the setup with delays and packet drops described in Section II. For example one can find a similar model to (16) but introduce the dependency on the variable q_k modeling the packet drops in the matrix L .

2.3. Stability notion

We define stability for system (12) in terms of the following auxiliary system obtained by considering the state of (12) only at times t_k^-

$$z_{k+1} = e^{A h_k} J_{p(z_k, k)} z_k, \quad k \in \mathbb{N}_0, \tag{18}$$

where $z_k := x(t_k^-)$, and $z_0 = x_0$. We say that (12) is *mean exponentially stable (MES)* if there exists constants $c > 0$ and $0 < \alpha < 1$ such that for any initial condition x_0 , we have that

$$\mathbb{E}[z_k^T z_k] \leq c \alpha^k z_0^T z_0, \quad \forall k \geq 0. \tag{19}$$

The same definition of MES is used for system (16). We assume that the following condition holds

$$e^{2\bar{\lambda}(A)t} r(t) < c e^{-\alpha_1 t} \text{ for some } c > 0, \alpha_1 > 0. \tag{20}$$

where $\bar{\lambda}(A)$ is the real part of the eigenvalues of A with largest real part and $r(t) := \mu((t, \gamma])$ denotes the survivor function. Assuming (20), we were able to prove in [6], considering only static protocols, that (19) is equivalent to the more usual notion of

mean exponential stability in continuous-time where one requires $\mathbb{E}[x(t)^T x(t)]$ to decrease exponentially. In the present paper we make no such assertion, although assuming (20) is still useful (e.g., (20) guarantees that (22) is bounded).

III. Main Results

For simplicity, we assume in Subsection 3.1 and 3.2, that there are no delays, i.e., $d_k = 0, \forall k$, and no packet drops, i.e., $p_{\text{drop}} = 0$, and in Subsection 3.3 we consider the general case.

3.1. Stability Result I and dynamic vs. static protocols

The following is our first stability result for (12), providing easy to test *sufficient* conditions for (12) to be Mean Exponentially Stable.

Theorem 1 *The system (12) with dynamic protocol (13) is MES if there exist scalars $\{0 \leq p_{ji} \leq 1, j, i \in \mathcal{M}_D\}$, with $\sum_{j=1}^{m_D} p_{ji} = 1, \forall i \in \mathcal{M}_D$, and $n_x \times n_x$ symmetric matrices $\{R_i > 0, i \in \mathcal{M}_D\}$ such that*

$$J_{d_1(i)}^T \left(\sum_{j=1}^{m_D} p_{ji} E(R_j) \right) J_{d_1(i)} - R_i < 0, \quad \forall i \in \mathcal{M}_D, \tag{21}$$

where

$$E(R_j) := \int_0^\gamma e^{A^T h} R_j e^{A h} \mu(dh). \tag{22}$$

□

This result can be used to analyze if a given protocol yields the networked control system stable or to synthesize a protocol that achieves this.

Analysis: Note first that a given dynamic protocol specified by $R_i > 0, i \in \mathcal{M}_D$, is equivalent to a dynamic protocol specified by

$$\tilde{R}_i = P + R_i > 0, \quad i \in \mathcal{M}_D, \tag{23}$$

where P can be any symmetric matrix such that $P + R_i > 0$. If we replace in (21) the matrices R_i by \tilde{R}_i , given by (23), we obtain that (21), (23) are LMIs in the variables P and p_{ji} (using the fact that $\sum_{j=1}^m p_{ji} = 1, \forall i \in \mathcal{M}_D$).

Synthesis: If we allow R_i to be variables in (21), then (21) are in general BMIs. In fact, if we chose a basis B_l for the linear space of symmetric matrices, we have $R_i = \sum_{l=1}^{n_s} b_{il} B_l$ and (21) depends on the products $p_{ji} b_{il}$. In this case the dynamic protocol, determined by the matrices R_i comes out from the solution to (21).

Remark 2 Stability condition (21) resembles a stability condition for Markov Jump Linear Systems [12]. Indeed, suppose that we choose protocol p for (12) according to the following stochastic rule:

$$\begin{aligned} \text{Prob}[\omega_{k+1} = j | \omega_k = i] &= \mu_{ij}, \quad i, j \in \mathcal{M}_D \\ p(x(t_k^-), k) &= d_1(\omega_k), \quad k \geq 0, \end{aligned} \quad (24)$$

where ω_k is a Markov Chain with $m_D \geq m$ states, $\sum_{j=1}^{m_D} \mu_{ji} = 1, \forall i \in \mathcal{M}_D$, and d_1 is described by (8). Then, it is well-known (cf. [12, Ch. 4]) that (18) with scheduling (24) is Mean Square Stable ($\lim_{k \rightarrow \infty} \mathbb{E}[x(t_k^-)^\top x(t_k^-)] = 0, \forall x_0$) if and only if there exists $n_x \times n_x$ symmetric matrices $\{R_i > 0, i \in \mathcal{M}_D\}$ such that (21) holds for $p_{ji} = \mu_{ji}, \forall i, j \in \mathcal{M}_D$. Note, however, that contrarily to protocol (24), protocol (6), (8) is a deterministic state-dependent protocol and Theorem 1 assures stability in the deterministic sense (19). \square

To state the next theorem, we need the following result which provides necessary and sufficient stability conditions under which (12) is Mean Exponentially Stable for a static protocol (14). The proof can be found in [6] and is omitted here. Let $\lfloor i+1 \rfloor := i+1$ if $i \in \{1, \dots, m_S - 1\}$ and $\lfloor i+1 \rfloor = 1$ if $i = m_S$. Let $\mathcal{M}_S := \{1, \dots, m_S\}$.

Theorem 3 The system (12), with static protocol (14) is MES if and only if there exists $n_x \times n_x$ symmetric matrices $\{R_i > 0, i \in \mathcal{M}_S\}$ such that

$$J_{s(i)}^\top E(R_{\lfloor i+1 \rfloor}) J_{s(i)} - R_i < 0, \forall i \in \mathcal{M}_S \quad (25)$$

where $E(R_{\lfloor i+1 \rfloor})$ is given as in (22). \square

The following result, which builds upon Theorems 1 and 3, establishes that if the networked closed loop is stable for a static protocol then we can provide a dynamic protocol for which the networked closed loop is also stable and is one of the main contributions of the paper. \square

Theorem 4 If the networked control system is MES for a static protocol with period m_S then there exists a dynamic protocol taking the form (6), with $m_D = m_S$, that yields the networked control system MES. \square

Proof. Since the stability conditions of Theorem 3 are necessary and sufficient, there exists a static protocol with period m_S that yields the networked control system MES if and only if there exists $\{R_i, i \in \mathcal{M}_S\}$ such that (25) holds for (12) with matrices defined by (15). This implies that if we consider a dynamic protocol with $m_D = m_S, I_j = \{k \in \mathcal{M}_S : s(k) = j\}, j \in \mathcal{M}$, then $d_1(i) = s(i)$, for $i \in \mathcal{M}_S$ and (21) holds with

$$p_{ji} = \begin{cases} 1, & \text{if } i < m_D \text{ and } j = i + 1, \\ 1, & \text{if } i = m_D \text{ and } j = 1, \\ 0 & \text{otherwise} \end{cases}$$

and with $\{R_i, i \in \mathcal{M}_S = \mathcal{M}_D\}$ taken to be the solution to (25). \blacksquare

From the proof of Theorem 4 we see that the matrices $\{R_i, i \in \mathcal{M}_D\}$ that characterize the dynamic protocol mentioned in its statement can be taken to be the solution to (25). Note that in the special case where $m_D = m = m_S$, the Theorem 4 states that if there exists a round-robin protocol with period $m_S = m$, i.e., each node only transmits exactly once in a period, that yields the networked control system MES, then one can find a quadratic protocols as introduced in [7] that also yields the networked control system MES.

Remark 5 The fact that the stability conditions of Theorem 3 are necessary and sufficient is key to obtain Theorem 4. In the work [4] a similar reasoning to Theorem 4 can be used to prove that if the stability conditions provided there for quadratic protocols (cf. [4, Th. 3]) hold then so do the stability conditions for a static protocol in the special case where each node transmits only once in a period (cf. [7, Th. 3]). However, since the conditions provided in [4] are only sufficient for the RR protocol, it does not allow to conclude that if a stabilizing static protocol exists then so does a dynamic protocol, as stated in Theorem 4. Although [7] does not explicitly presents stability conditions for a static protocol, the same remarks should apply, since convex over-approximations introduce conservativeness. \square

3.2. Stability Result II and observer-protocol design

The following is our second stability result for (12). Similarly to Theorem 1 this theorem provides easy to test sufficient conditions for (12) to be Mean Exponentially Stable. However, it will allow us to obtain different results than Theorem 1.

Theorem 6 The system (12) with dynamic protocol (13) is MES if there exists an $n_x \times n_x$ symmetric matrix $W > 0$, scalars $\{c_{ij} \geq 0, i, j \in \mathcal{M}_D, i \neq j\}$ and $n_x \times n_x$ matrices $R_i, i \in \mathcal{M}_D$ such that

$$J_{d(i)}^T E(W) J_{d(i)} + \sum_{j=1, j \neq i}^{m_D} c_{ij} (R_j - R_i) - W < 0, \forall i \in \mathcal{M}_D \quad (26)$$

where $E(W) := \int_0^\gamma (e^{Ah})^T W e^{Ah} \mu(dh)$. □

Given a quadratic protocol, i.e., specific values for the matrices R_i , testing if (26) holds is an LMI feasibility problem. To design a protocol for which mean exponential stability of the networked control system is guaranteed, we can take the $\{R_i, i \in \mathcal{M}_D\}$ as additional unknowns and (26) should now be viewed as a BMI feasibility problem.

The proof of Theorem 6 builds upon establishing that if there exists a positive definite matrix W , positive constants c_{ij} and matrices R_i such that (26) holds then the quadratic function

$$V(x) := x^T W x \quad (27)$$

is a stochastic Lyapunov function for system (18) (which models (12) at sampling times) in the sense that the following condition holds for (18)

$$\mathbb{E}[V(z_{k+1})] - V(z_k) \leq -z_k^T Z z_k, \forall z_k \in \mathbb{R}^{n_x}, \quad (28)$$

for some $Z > 0$. The next result shows that under certain conditions, which include the case $m_D = m = 2$, i.e., only two nodes pertaining to the closed loop access the network, the converse holds. Let $\text{co}(\mathcal{A})$ denote the convex hull of a set \mathcal{A} , and for each $i \in \mathcal{M}_D$ define the function

$$g_0^i(y) := y^T (W - J_{d(i)}^T E(W) J_{d(i)}) y$$

and the $m_D - 1$ functions

$$g_j^i(y) = y^T (R_j - R_i) y, \quad j \in \mathcal{M}_D - \{i\}.$$

Define also the following sets in \mathbb{R}^{m_D}

$$\mathcal{K}^i := \{(g_0^i(y), g_1^i(y), \dots, g_{i-1}^i(y), g_{i+1}^i(y), \dots, g_{m_D}^i(y)) | y \in \mathbb{R}^{m_D}\}, \quad i \in \mathcal{M}_D,$$

and

$$\mathcal{N} := \{(\eta_0, \eta_1, \dots, \eta_{m_D}) | \eta_0 < 0, \eta_k > 0, 1 \leq k \leq m_D\}.$$

Theorem 7 Suppose that dynamic protocol (13) is regular. Then, if

$$\mathcal{K}^i \cap \mathcal{N} = \emptyset \Rightarrow \text{co}(\mathcal{K}^i) \cap \mathcal{N} = \emptyset, \forall i \in \mathcal{M}_D, \quad (29)$$

there exists an $n_x \times n_x$ symmetric matrix $W > 0$, scalars $\{c_{ij} \geq 0, i, j \in \mathcal{M}_D, i \neq j\}$ and $n_x \times n_x$ matrices $R_i, i \in \mathcal{M}_D$ such that (26) holds if and only if there exists a quadratic stochastic Lyapunov function taking the form (27) such that (28) holds. In particular (29) holds if $m_D = 2$. □

The proof of Theorem (7) relies on the S-Procedure (see, e.g., [13]) which is a relaxation technique that can be used to provide easy to check stability conditions for linear systems with quadratic constraints. In particular, the condition (29) is a condition for the S-Procedure to be lossless, and is always satisfied in the case in which there is only one quadratic constraint ($m_D = 2$).

We show next that Theorem 6 allows to extend the observer-protocol design proposed in [8].

3.2.1. Observer Design

Suppose that we wish to estimate the state of the following plant

$$\dot{x}_P(t) = A_P x_P(t), \quad y(t) = C_P x_P(t), \quad x_P(0) = x_{P0}$$

where the m outputs $y(t) = (y_1, \dots, y_m)$, $y_i \in \mathbb{R}^{s_i}$ are sent through a network that imposes i.i.d. intervals between transmissions to a remote observer. As in Section II, we denote by μ the measure that defines the inter-transmissions times $h_k = t_{k+1} - t_k$ and we let $\mathcal{M} = \{1, \dots, m\}$. Let also $\Psi_j := \text{diag}([0_{s_1}, \dots, I_{s_j}, \dots, 0_{s_m}])$, for $j \in \mathcal{M}$. A natural model based linear remote observer for this system is defined by

$$\dot{\hat{x}}(t) = A_P \hat{x}(t) + L_k \Psi_{c(x_e(t_k^-))} (C_P \hat{x}(t_k^-) - y(t_k^-)), \quad (30)$$

where the observer gains L_k to be designed are allowed to depend on the index k and the map

$$c(x_e(t_k^-)) := \text{argmin}_{j \in \mathcal{M}} x_e(t_k^-)^T C_P^T S_j C_P x_e(t_k^-) \quad (31)$$

determines which node transmits at t_k based on the estimation error $x_e(t_k^-) := \hat{x}(t_k^-) - x_P(t_k^-)$, where $\{S_j, j \in \mathcal{M}\}$ is a set of m matrices. As argued in [8], the sensors should run a replica of the remote observer to access $\hat{x}(t)$, which allows each node to encode in the message arbitration field $x_e(t_k^-)^T C_P^T S_j C_P x_e(t_k^-)$, where $C_P x_e(t_k^-) = C_P \hat{x}(t_k^-) - y_j(t_k^-)$, $j \in \mathcal{M}$.

The resulting estimation error $x_e := \hat{x} - x_P$ evolves according to

$$\dot{x}_e(t) = A_P x_e(t) + L_k \Psi_{c(x_e(t_k^-))} C_P x_e(t_k^-). \quad (32)$$

We can cast this problem into the framework of (12) with dynamic protocol (13) by adding an auxiliary variable v that holds the value of $x_e(t_k)$ between transmission times, considering $x = (x_e, v)$ and

$$\begin{aligned} A &= \begin{bmatrix} A_P & I_{n_P} \\ 0_{n_P} & 0_{n_P} \end{bmatrix}, \\ J_i &= \begin{bmatrix} I_{n_P} & 0_{n_P} \\ 0_{n_P} & 0_{n_P} \end{bmatrix} + \begin{bmatrix} 0 \\ L_k \end{bmatrix} [\Psi_i C_P \quad 0], \\ R_i &= \begin{bmatrix} C_P^T S_i C_P & 0 \\ 0 & 0_{n_P} \end{bmatrix}, \quad 1 \leq i \leq m = m_D. \end{aligned} \quad (33)$$

In the following theorem, we propose a method to obtain observer gains L_k that yield the networked control system MES. To state the result we need the following assumption:

$$H(s) := \int_0^s e^{A_P r} dr \text{ is invertible for every } s \in [0, \gamma]. \quad (34)$$

While this assumption holds for a large class of matrices A_P , it is possible to construct examples where it does not, as in the case where $\gamma > s = 2\pi$ and $A_P = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}$, in which case $H(s) = 0$.

Theorem 8 Suppose that (34) hold. If there exists a $n_P \times n_P$ symmetric matrix $P > 0$, a $m \times m$ matrix Y , a $n_P \times m$ matrix M , $m \times m$ matrices $\{S_i, i \in \mathcal{M}\}$, and scalars $\{c_{ij} \geq 0, i, j \in \mathcal{M}\}$, such that

$$\begin{aligned} F(P) + DM\Psi_i C_P + (DM\Psi_i C_P)^T + C_P^T Y C_P + (35) \\ \sum_{j=1, j \neq i}^m c_{ij} (C_P^T S_j C_P - C_P^T S_i C_P) - P < 0, \quad \forall i \in \mathcal{M} \\ \begin{bmatrix} P & M \\ M^T & Y \end{bmatrix} > 0, \end{aligned} \quad (36)$$

where $F(P) := \int_0^\gamma e^{A_P^T r} P e^{A_P r} \mu(dr)$ and $D := \int_0^\gamma e^{A_P r} \mu(dr)$, then we have that the observer gain $L_k = H(h_k)^{-1} P^{-1} M$ yields (12) with matrices (33) MES. \square

Note that our proposed observer gain L_k depends on the length h_k of the time interval $\{t_{k+1} - t_k\}$, which

is not known at time $t_k \leq t < t_{k+1}$ (30). In practice this results in a delay in constructing the state estimate that never needs to exceed h_k since the state of the remote observer (30) can only be updated with measurement $y(t_k)$ at time t_{k+1} at which h_k can be computed.

Similarly to the Theorem 6, the conditions of the Theorem 8 can be used to investigate the stability of a given protocol determined by matrices R_j , in which case the problem reduces to an LMI feasibility problem, or they can be used to design a protocol, in which case one needs to solve a BMI feasibility problem.

Remark 9 When the intervals between transmission are constant, one can show that the stability conditions (35) and (36) are equivalent to the ones given in [8], where such an assumption is made. In this case, the matrices L_k do not depend on k , and can therefore be computed off-line.

3.3. Extensions to handle delays and packet drops

Theorems 6 and 1 can be extended to the case where the network introduces packet drops and delays modeled by (16) with matrices (17). We state these extensions next.

Theorem 10 System (16) with dynamic protocol (13) is MES if there exist scalars $\{0 \leq p_{ji} \leq 1, j, i \in \mathcal{M}_D\}$, with $\sum_{j=1}^{m_D} p_{ji} = 1, \forall i \in \mathcal{M}_D$, and $n_x \times n_x$ symmetric matrices $\{R_i > 0, i \in \mathcal{M}_D\}$ such that

$$\sum_{l=1}^{n_q} w_l (K_{d_1(i)}^l)^T \left(\sum_{j=1}^{m_D} p_{ji} E(R_j) \right) K_{d_1(i)}^l - R_i < 0, \quad \forall i \in \mathcal{M}_D,$$

where

$$E(R_j) := \int_0^\gamma \int_0^h (e^{Ah-s} L e^{As})^T R_j e^{Ah-s} L e^{As} \chi(h, ds). \quad (37)$$

\square

Theorem 11 System (16) with dynamic protocol (13) is MES if there exists an $n_x \times n_x$ symmetric matrix $W > 0$, scalars $\{c_{ij} \geq 0, i, j \in \mathcal{M}_D, i \neq j\}$ and $n_x \times n_x$ matrices $R_i, i \in \mathcal{M}_D$ such that

$$\begin{aligned} \sum_{l=1}^{n_q} w_l (K_{d_1(i)}^l)^T E(W) K_{d_1(i)}^l + \\ \sum_{j=1, j \neq i}^m c_{ij} (R_j - R_i) - W < 0, \quad \forall i \in \mathcal{M}_D, \end{aligned}$$

where $E(W)$ is defined as in (37).

IV. Networked Control Results

In this section we show that Theorems 6 and 11 reduce the conservatism of the results in [3], [5], and [7]. These three works use the same benchmark problem for the control of a batch reactor, where the plant (1) and controller (2) matrices are given by

$$A_P = \begin{bmatrix} 1.38 & -0.2077 & 6.715 & -5.676 \\ -0.5814 & -4.29 & 0 & 0.675 \\ 1.067 & 4.273 & -6.654 & 5.893 \\ 0.048 & 4.273 & 1.343 & -2.104 \end{bmatrix},$$

$$B_P = \begin{bmatrix} 0 & 0 \\ 5.679 & 0 \\ 1.136 & -3.146 \\ 1.136 & 0 \end{bmatrix}, C_P = \begin{bmatrix} 1 & 0 & 1 & -1 \\ 0 & 1 & 0 & 0 \end{bmatrix}.$$

$$A_C = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}, B_C = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix},$$

$$C_C = \begin{bmatrix} -2 & 0 \\ 0 & 8 \end{bmatrix}, D_C = \begin{bmatrix} 0 & -2 \\ 5 & 0 \end{bmatrix}.$$

Only the two outputs are sent through the network, i.e., $u(t) = \hat{u}(t)$. The network imposes i.i.d. intervals between transmissions, possibly packet drops and no delays. The networked control closed loop can be written as in (12), (15) in the absence of drops and as in (16)- (17) when drops occur. Thus, the stability of the networked control system can be tested by Theorems 1, 6, and 10, 11. The results are shown in the Table 1, considering two distributions μ for the inter-transmissions intervals h_k : uniform in the interval $[0, \gamma]$, and exponential with expected value $1/\lambda_{\text{exp}}$.

From Table 1 we can conclude that our results allow to significantly reduce the conservatism of the conditions in [5] and [3] for the same benchmark examples. The results in [7] are very close to the ones obtained with Theorem 1 and both outperform the results obtained with Theorem 6.

In Table 2, we show the results obtained by allowing R_i in Theorem 1 to be additional variables, i.e., the protocol is to be designed. Note that Theorem 4 assures that the values obtained with Theorem 1 for the maximum support of a uniform distribution that preserves stability when a dynamic protocol (obtained from solving (21)) is utilized, are larger than the ones obtained with the necessary and sufficient conditions provided by Theorem 3 for the static protocol, which matches well with the results in Table 2.

V. Conclusions

We provided stability results for networked control systems with stochastic intervals between

transmissions, delays, and packet drops. Our main result was to show that one can analytically prove that dynamic protocols preserve stability for larger sampling intervals between transmission than static protocols, and therefore less communication and control computations are required for such protocols in networked control systems.

Motivated by recent research (cf., e.g., [14], [15], [16]) on H_2 optimal problems in the context of networked control systems a possible line for future research is to consider related optimal control problems in the scenarios addressed in the present paper.

A. Proofs

Proof. (of Theorem 1) The discrete-time process z_k , described by (18), can be easily shown to be a Markov process due to the i.i.d. assumption on h_k . In particular

$$\mathbb{E}_{z_k} [\mathbb{E}_{z_{k+l}} [V(z_{k+l+m})]] = \mathbb{E}_{z_k} [V(z_{k+l+m})] \quad (38)$$

for any bounded measurable function V , where \mathbb{E}_{z_k} denotes expectation given z_k , i.e., $\mathbb{E}_{z_k}[\cdot] := \mathbb{E}[\cdot | z_k]$. If one can find a function V and positive constants c_1, c_2, c_3 , such that

$$c_1 \|z\|^2 \leq V(z) \leq c_2 \|z\|^2, \forall z \in \mathbb{R}^{n_x} \quad (39)$$

and

$$\mathbb{E}_{z_k} [V(z_{k+1})] - V(z_k) \leq -c_3 \|z_k\|^2, \forall z_k \in \mathbb{R}^{n_x} \quad (40)$$

then we can prove that

$$\mathbb{E}[z_k^T z_k] \leq c \alpha^k z_0^T z_0, \forall k \geq 0 \text{ for some } 0 < \alpha < 1, c > 0. \quad (41)$$

which implies MES for (12) according to the definition (19) since $x(t_k) = J_i z_k$ for some $i \in \mathcal{M}$. In fact if (39) and (40) hold then

$$E_{z_k}[V(z_{k+1})] \leq \alpha V(z_k) \quad (42)$$

where $0 < \alpha = 1 - \frac{c_3}{c_2} < 1$ must be greater than zero since V is positive. From (38) and (42) we can conclude that

$$E_{z_0}[V(z_k)] \leq \alpha^k V(z_0). \quad (43)$$

From (39) and (43) we obtain

$$E_{z_0}[\|z_k\|^2] \leq \frac{c_2}{c_1} \alpha^k \|z_0\|^2, \quad k \geq 0.$$

Take $V(z_k) := \min_{i \in \mathcal{M}_D} z_k^T R_i z_k$, which satisfies (39) since $R_i > 0 \quad \forall i \in \mathcal{Q}$. Suppose that z_k is such that $i = d_2(z_k) = \operatorname{argmin}_{j \in \mathcal{M}_D} z_k^T R_j z_k$, i.e., $V(z_k) = z_k^T R_i z_k$. Note that, in the case where the minimum is achieved simultaneously for several value of the index i , any of these indexes can be chosen without affecting the present proof. Then, for any $p_{ji} \geq 0 : \sum_{j=1}^{m_D} p_{ji} = 1$, we have that

$$\begin{aligned} \mathbb{E}_{z_k}[V(z_{k+1})] &= \mathbb{E}_{z_k}[\min_{j \in \mathcal{M}_D} z_k^T J_{d_1(i)}^T e^{A^T h} R_j e^{Ah} J_{d_1(i)} z_k] \\ &\leq \mathbb{E}_{z_k}[\sum_{j=1}^{m_D} p_{ji} z_k^T J_{d_1(i)}^T e^{A^T h} R_j e^{Ah} J_{d_1(i)} z_k] \\ &= z_k^T J_{d_1(i)}^T \sum_{j=1}^{m_D} p_{ji} E(R_j) J_{d_1(i)} z_k \end{aligned} \quad (44)$$

Suppose we choose p_{ji} such that (21) holds, i.e.,

$$J_{d_1(i)}^T \sum_{j=1}^{m_D} p_{ji} E(R_j) J_{d_1(i)} - R_i = -Q_i$$

for some $Q_i > 0$. Then from (44) we conclude that $\mathbb{E}_{z_k}[V(z_{k+1})] - V(z_k) \leq -z_k^T Q_i z_k$, $i = d_2(z_k)$, which implies (40) and concludes the proof. ■

Proof. (of Theorem 6) As in the proof of the Theorem 1 it suffices to find a function V such that (39), (40) hold. Take $V(z) = z^T W z$, where W is the solution to (26) and suppose that $i = \operatorname{argmin}_{j \in \mathcal{M}} z^T R_j z$. Then

$$\begin{aligned} \mathbb{E}_{z_k}[V(z_{k+1})] - V(z_k) &= z_k^T [J_{d_1(i)}^T E(W) J_{d_1(i)} - W] z_k, \\ &= -z_k^T [\sum_{j=1, j \neq i}^{m_D} c_{ij} (R_j - R_i) + Q_i] z_k \end{aligned} \quad (45)$$

where $Q_i > 0$. Since $i = \operatorname{argmin}_{j \in \mathcal{M}} z_k^T R_j z_k$ we have that $z_k^T [\sum_{j=1, j \neq i}^{m_D} c_{ij} (R_j - R_i)] z_k \geq 0$ for every $z_k \in \mathbb{R}^{n_x}$ and therefore from (45) we conclude that V satisfies (40). It is also clear that V satisfies (39), which concludes the proof. ■

Proof. (of Theorem 7) If for a given $z_k, i \in \mathcal{M}_D$ is such that $i = \operatorname{argmin}_{j \in \mathcal{M}_D} z_k^T R_j z_k$, which is equivalent to

$$g_j^i(z_k) \geq 0, \quad \forall j \in \mathcal{M} - \{i\}, \quad (46)$$

then we have that $z_{k+1} = e^{A_k} J_{d(i)} z_k$ in which case (28) boils down to

$$g_0^i(z_k) > 0. \quad (47)$$

The fact that the dynamic protocol is regular implies that there exists at least one y such that (46) holds with strict inequality. Then, a straightforward adaptation of the lossless S-Procedure theorem provided in [13, Th.2] to handle strict inequalities in the objective function $g_0^i(y)$ assures that, under condition (29), (47) holds if and only if there exists $c_{ij} \geq 0, j \in \mathcal{M}_D - \{i\}$ such that

$$g_0^i(y) - \sum_{j \in \mathcal{M}_D - \{i\}} c_{ij} g_j^i(y) > 0, \quad \forall y \in \mathbb{R}^{n_x}. \quad (48)$$

The result then follows by noticing that (48) is equivalent to (26). The fact that (29) holds if $m_D = 2$ (in which case there is only one quadratic constraint) follows from [13, Th. 3]. ■

Proof. (of Theorem 8) We first prove that if there exists $P > 0$ such that

$$\begin{aligned} \int_0^\gamma (e^{A_P h} + H(h) L_k \Psi_i C_P)^T P \dots \\ \dots (e^{A_P h} + H(h) L_k \Psi_i C_P) \mu(dh) \\ + \sum_{j=1, j \neq i}^m c_{ij} (C_P^T S_j C_P - C_P^T S_i C_P) - P < 0 \end{aligned} \quad (49)$$

then (26) holds for (12) with matrices (33). Note that we can assume that $d_1(i) = i, \forall i \in \mathcal{M}$ since if this is not the case we can relabel the sensor nodes in such a way that this holds. For A, J_i given by (33) we have that

$$e^{Ah} J_i = \begin{bmatrix} e^{A_P h} + H(h) L_k \Psi_i C_P & 0 \\ L_k \Psi_i C & 0 \end{bmatrix}.$$

Using this expression and considering $W = \operatorname{diag}([P \in I_{n_P}])$ in (26) where P satisfies (49) and

ϵ is a given positive constant we have

$$\int_0^\gamma \begin{bmatrix} B(h) & 0 \\ 0 & 0 \end{bmatrix} \mu(dh) - \begin{bmatrix} P & 0 \\ 0 & \epsilon I_{n_P} \end{bmatrix} + \sum_{j=1, j \neq i}^m c_{ij} \begin{bmatrix} C_P^\top S_j C_P - C_P^\top S_i C_P & 0 \\ 0 & 0_{n_P} \end{bmatrix} < 0, \quad \forall i \in \mathcal{M} \quad (50)$$

where

$$B(h) = \epsilon(L_k \Psi_i C_P)^\top (L_k \Psi_i C_P) + (e^{A_P h} + H(h) L_k \Psi_i C_P)^\top P (e^{A_P h} + H(h) L_k \Psi_i C_P).$$

From this expression we conclude that if (49) holds then (50) holds for sufficiently small ϵ . Set $L_k = H(h_k)^{-1} P^{-1} M$ for a $n_P \times m$ matrix. Then (49) can be written as

$$F(P) + DM \Psi_i C_P + (DM \Psi_i C_P)^\top + C_P^\top M P^{-1} M C_P + \sum_{j=1, j \neq i}^m c_{ij} (C_P^\top S_j C_P - C_P^\top S_i C_P) - P < 0, \quad \forall i \in \mathcal{M}. \quad (51)$$

If we let $Y > 0$ be such that $M^\top P^{-1} M < Y$, which applying the Shur complement can be seen to be equivalent to (36), we see that if (35) holds then (51) holds, which concludes the proof. ■

Proof. (of Theorem 10) The proof is obtained by following the same steps of Theorem 1 and by noticing that using a similar reasoning to (44) one obtains

$$\mathbb{E}_{z_k} [V(z_{k+1})] \leq \sum_{l=1}^{n_q} w_l (K_{d_1(i)}^l)^\top \left(\sum_{j=1}^{m_D} p_{ji} E(R_j) \right) K_{d_1(i)}^l.$$

■

Proof. (of Theorem 11) The proof is obtained by following the same steps of Theorem 6 and by noticing that in (45)

$$\mathbb{E}_{z_k} [V(z_{k+1})] = \sum_{l=1}^{n_q} w_l (K_{d_1(i)}^l)^\top E(W) K_{d_1(i)}^l.$$

Table 1. Stability results for the batch reactor example-MEF-TOD and Round Robin protocol. NA stands for Not Available

	Dynamic Protocol		Static Protocol	
	no drops	$p = 0.5$	no drops	$p = 0.5$
Max. γ :				
$h_k \sim \text{Uni}(\gamma)$				
Results from [3]	NA	NA	NA	NA
Results from [5]	0.0372	0.0170	0.0517	0.0199
Results from [7]	0.11	NA	NA	NA
Ths. 6 and 11	0.0550	0.024	NA	NA
Ths. 1	0.111	NA	NA	NA
Th. 3	NA	NA	0.112	0.0385
Max. $1/\lambda_{\text{exp}}$:				
$h_k \sim \text{Exp}(\lambda_{\text{exp}})$				
Results from [3]	0.0095	0.0046	NA	NA
Results from [5]	0.0158	0.00795	0.0217	0.00924
Results from [7]	NA	NA	NA	NA
Ths. 6 and 11	0.0226	0.01124	NA	NA
Ths. 1	0.0357	NA	NA	NA
Th. 3	NA	NA	0.0417	0.0188

Table 2. Stability results for the batch reactor example-Protocol design, no packet drops

	Dyn. Prot. Design (Th.1)	Static Prot. (Th.3)
Max. γ :		
$h_k \sim \text{Uni}(\gamma)$	0.140	0.112
