Nonlinear Predictive Models

- Nonlinear Autoregressive Models

\[ X_t = h(X_{t-1}, X_{t-2}, \ldots, X_{t-p}) + e_t \]

The best prediction of \( X_t \) given \( X_{t-1}, \ldots, X_{t-p} \) is its conditional mean

\[ \hat{X}_t = E(X_t \mid X_{t-1}, \ldots, X_{t-p}) \]
\[ = h(X_{t-1}, X_{t-2}, \ldots, X_{t-p}) \]

where \( h(.) \) is an unknown smooth function
A feedforward network is a nonlinear approximation to \( h \) given by

\[
\tilde{X}_t = h(X_{t-1}, X_{t-2}, \ldots, X_{t-p}) = \sum_{i=1}^{1} W_i f \left( \sum_{j=1}^{p} W_{ij} X_{t-j} \right)
\]

The weight matrix is lower diagonal and will allow no feedback. Thus the feedforward network serves as nonlinear mapping from previous observation onto predictions of future observations. The function \( f(x) \) is typically a sigmoid.

The parameters \( W_i \) and \( W_{ij} \) are estimates from a training sample \( x^{o_i}, \ldots, x^{o_N} \), thereby obtaining an estimate of \( \overline{h} \) and \( h \). Estimates are obtained by minimizing the sum of square residuals

\[
\sum_{t=1}^{n} (x_t - \tilde{x}_t)^2
\]

by backpropogation.
Nonlinear Predictive Models

• Nonlinear ARMA Models

\[ X_t = h(X_{t-1}, X_{t-2}, \ldots, X_{t-p}, e_{t-1}, e_{t-2}, \ldots, e_{t-p}) + e_t \]

Predict:

\[ \tilde{X}_t = \tilde{h}(X_{t-1}, X_{t-2}, \ldots, X_{t-p}, \tilde{e}_{t-1}, \tilde{e}_{t-2}, \ldots, \tilde{e}_{t-p}) \]

If the \( \tilde{h}(.) \) is chosen, then a recurrent network can approximate it as

\[ \tilde{X}_t = h(X_{t-1}, X_{t-2}, \ldots, X_{t-p}) = \sum_{i=1}^{1} W_{i} f \left( \sum_{j=1}^{p} W_{ij} x_{t-j} + \sum_{j=1}^{q} W'_{ij} (x_{t-j} - \tilde{x}_{t-j}) \right) \]

This model is a special case of the fully connected recurrent network

\[ \tilde{X} = \sum_{i=1}^{1} W_{i} f \left( \sum_{j=1}^{n} W''_{ij} x_{t-j} \right) \]

where \( w''_{ij} \) are coefficients of a full matrix
Signal Modeling and Prediction by Neural Networks

- Given (by experimental measurements or by simulation) \(X(.)\) at discrete times in some time window containing times less than \(t\), predict \(X(t+P)\), where \(P\) is some prediction time step in the future.

- Use backpropogation and neural network architecture for constructing a function

\[O(t + P) = f(I_1(t), I_2(t - \Delta)........, I_m(t - m\Delta))\]

Where

- \(O(t+P)\): the output of a single neuron in the output layer
- \(I_1 \rightarrow I_m\): Input neurons that take on values \(x(t), x(t-\Delta), .. x(t-m\Delta)\)
- \(\Delta\): the time delay
• The $O(t+p)$ takes the values $X(t+P)$

• For Feedforward networks, select input values:

\[
\begin{align*}
I_1 & = x(t_p) \\
I_2 & = x(t_p - \Delta) \\
I_3 & = x(t_p - 2\Delta) \\
\vdots & = \vdots \\
I_m & = x(t_p - (m-1)\Delta)
\end{align*}
\]

with associated output values $O = X(t_p + P)$ for discrete times labelled by $t_p$. 
• Takens Theorem (1981) provides a guide for choosing m such that

\[ d_A < m+1 < 2d_A+1 \]

where \( d_A \) is the embedding dimension

• Takens theorem provides no information on \( \Delta \)

• This prediction procedure is the nonlinear extension of the linear Widrow Hoff Algorithm
In the case of a linear causal model, the output at any time instant is a linear combination of the present and past values of the input. In other words,

$$X_t = \sum_{u=0}^{\infty} h_u e_{t-u}$$

For a non-linear causal model, the output at any time instant is a non-linear function of the present and the past values of the input.

$$X_t = f(e_t, e_{t-1}, e_{t-2}, \ldots)$$

If we assume that $f$ is sufficiently well behaved so that it can be expanded in a Taylor series about the point $O=(0,0,0)$, then we can expand the RHS of the above expression and write,
The Volterra Series

\[ X_t = \mu + \sum_{u=0}^{\infty} g_u e_{t-u} + \sum_{u=0}^{\infty} \sum_{v=0}^{\infty} g_{uv} e_{t-u} e_{t-v} + \sum_{u=0}^{\infty} \sum_{v=0}^{\infty} \sum_{w=0}^{\infty} g_{uvw} e_{t-u} e_{t-v} e_{t-w} + \ldots \]

where,

\[ \mu = f(0), \quad g_u = \left( \frac{\delta f}{\delta e_{t-u}} \right)_0, \quad g_{uv} = \left( \frac{\delta^2 f}{\delta e_{t-u} \delta e_{t-v}} \right)_0, \]

\[ g_{uvw} = \left( \frac{\delta^3 f}{\delta e_{t-u} \delta e_{t-v} \delta e_{t-w}} \right)_0, \quad \text{etc.,} \]

This expansion is known as (discrete time) Volterra Series, and it provides an important type of representation for non-linear models.
Here we consider the Second order Volterra Filter (SVF), that is the above series reduced to just the first three terms.

Let \( x(n) \) be the input to the filter at time instant ‘\( n \)’. Then the output is,

\[
y(n) = A^t X(n) + X^t (n) B(n) X(n)
\]

where

\[
X(n) = [x(n), x(n-1), \ldots, x(n-m+1)]^t
\]

A and B are the linear and the quadratic weights of length \( m \) and order \( m \) respectively.

\[
A = [a(0), a(1), \ldots, a(m-1)]^t
\]

\[
B = \begin{bmatrix}
    b(0,0) & \ldots & b(0,m-1) \\
    \ldots & \ldots & \ldots \\
    b(m-1,0) & \ldots & b(m-1,m-1)
\end{bmatrix}
\]
Many algorithms exist for updating the linear and quadratic weights of a SVF. The basic scheme is as shown in the above figure. The input $x(n)$ and its past $m-1$ samples are fed to the filter. The output of the filter is compared with the desired signal and the error signal obtained is used to update the linear and quadratic weights. The desired signal for the prediction problem will be the time series sample one time instant ahead. The weights are frozen after training.
The State-Dependent Model Approach

Let us assume that the input $X_t$ can be described in terms of finitely many values of the past input $\{X_t\}$ and output $\{e_t\}$
Then we may write,

$$X_t = h(X_{t-1}, X_{t-2} \ldots, X_{t-p}, e_{t-1}, e_{t-2} \ldots, e_{t-p}) + e_t$$

Assuming that the function $h$ is analytic, we may expand the RHS of the above equation in a Taylor series about an arbitrary but fixed point $t_0$. Using only a first order expansion, we obtain

$$X_t = h(X_{t0-1}, X_{t0-2} \ldots, X_{t0-p}, e_{t0-1}, e_{t0-2} \ldots, e_{t0-p})$$

$$+ \sum_{u=1}^{k} f_u(x_{t-1})(X_{t-u} - X_{t0-u}) + \sum_{u=1}^{k} g_u(x_{t-1})(e_{t-u} - e_{t0-u}) + e_t$$

where, $x_t$ denotes the state vector at time $'t'$

$$x_t = [e_{t-l+1}, \ldots, e_t, X_{t-l+1}, \ldots, X_t]$$

and $f_u, g_u$ depend on the first order partial derivatives of $h$. 
We can now rewrite the above equation in the form

\[ X_t + \sum_{u=1}^{k} \phi_u(x_{t-1})X_{t-u} = \mu(x_{t-1}) + e_t + \sum_{u=1}^{l} \psi_u(x_{t-1})e_{t-u} \]

We call this equation a State-dependent Model of order \((k,l)\)

Augmenting the state vector with a constant unity to take care of \(\mu\) in the SDM, we have,

\[ X_t = h[1, e_{t-l+1}, \ldots, e_t, X_{t-k+1}, \ldots, X_t] \]

Let us denote the components of \(x_t\) by

\[ x_t = (x_t^{(1)}, x_t^{(2)}, \ldots, x_t^{(m)}) \]

where

\[ x_t^{(1)} = 1, \quad x_t^{(2)} = e_{t-l+1}, \ldots, \quad x_t^{(m)} = x_t \quad (m=k+l+1) \]
The State-Dependent Model Approach (Contd.)

We may then write

$$\Delta x_t = \left(\Delta x_t^{(1)}, \Delta x_t^{(2)}, \ldots, \Delta x_t^{(m)}\right)'$$

$$\Delta x_t^{(1)} = 0.$$ 

The simplest non-trivial assumption that we can make about the parameters $\mu$, $\phi$, and $\psi$ is that each is a linear function of the state vector $x_t$, so that we may write

$$\psi_u (x_{t+1}) = \psi_u (x_t) + \Delta x_{t+1}^T \beta_u^{(t+1)}$$

$$\phi_u (x_{t+1}) = \phi_u (x_t) + \Delta x_{t+1}^T \gamma_u^{(t+1)}$$

$$\mu (x_{t+1}) = \mu (x_t) + \Delta x_{t+1}^T \alpha_u^{(t+1)}$$
The State-Dependent Model Approach (Contd.)

The basic strategy is to allow $\beta_u(t)\gamma_u(t)$ and $\alpha_u(t)$ to wander in the form of ‘random walks’, and the estimation procedure would then determine, for each $t$, those values of $\beta_u(t)\gamma_u(t)$ and $\alpha_u(t)$ which would minimize the discrepancy between the observed value of $X_{t+1}$ and its predictor $X_{t+1}$, computed from the model. The estimation procedure is thus based on a sequential type of algorithm, similar in the nature to the ‘Kalman filter’ algorithm.

The time series data considered in the computer simulations all fall under basically “AR” type of SDMs. Hence a Kalman recursion is now developed for this model. The approach followed can readily be extended to the more general “ARMA” type SDM.

An “AR” SDM takes the form

$$X_t = \mu_{t-1} - \phi_{1,t-1}X_{t-1} - \phi_{2,t-1}X_{t-2}, \ldots, -\phi_{k,t-1}X_{t-k} + e_t$$

where

$$\mu_t = \mu_{t-1} + \alpha_1^{(t)}\Delta x_t^{(2)} + \alpha_2^{(t)}\Delta x_t^{(3)} \ldots + \alpha_k^{(t)}\Delta x_t^{(k+1)}$$

$$= \mu_{t-1} + \Delta x_t^{(T)}\alpha^{(t)}$$

And for each $u$,

$$\phi_{u,t} = \phi_{u,t-1} + \gamma_{u1}^{(t)}\Delta x_t^{(2)} + \gamma_{u2}^{(t)}\Delta x_t^{(3)} \ldots, + \gamma_{uk}^{(t)}\Delta x_t^{(k+1)}$$

$$= \phi_{u,t-1} + \Delta x_t^{T}\gamma_u^{(t)}$$

and

$$(\alpha^{(t)} : \gamma_k^{(t)} \ldots \gamma_k^{(t)}) = (\alpha^{(t-1)} : \gamma_k^{(t-1)} \ldots \gamma_k^{(t-1)}) + V_t$$
$V_t$ is a matrix having a multivariate normal distribution with zero means and variance-covariance matrix $\Sigma V$

We can now rewrite 1 in the form:

$$X_t = H_t \Theta_t + e_t$$

where $H_t$ is a 1 by $(k+1)^2$ row vector given by,

$$H_t = (1, -X_{t-1}, \ldots, -X_{t-k}; 0, 0, \ldots, 0),$$

(there are $k(k + 1)$ 0s in the $H_t$)

and $\Theta_t$ is a $(k+1)^2$ by 1 column vector given by,

$$\Theta_t = (\mu_{t-1}, \phi_{1,t-1}, \phi_{2,t-1}, \ldots, \phi_{k,t-1}; \alpha^{(t)}T, \gamma_1^{(t)}T, \gamma_2^{(t)}T \ldots, \gamma_k^{(t)}T)^T$$

The evolution of $\Theta_t$ over time is given by

$$\Theta_t = F_{t-1} \Theta_{t-1} + W_t$$

where the $(k+1)^2$ by $(k+1)^2$ matrix $F_{t-1}$ is given by
The State-Dependent Model Approach (Contd.)

\[ F_{t-1} = \begin{bmatrix} I_{k=1} & \Delta x_{t-1}^T \\ 0 & I_{k(k+1)} \end{bmatrix} \begin{bmatrix} \Delta x_{t-1}^T \\ 0 \end{bmatrix} \]

\[ W_t = (0,0,\ldots,0, v_{1,t}^T, \ldots, v_{k+1,t}^T)^T, \]

\[ v_{1,t}, \ldots, v_{k+1,t} \] being the columns of \( V_t \).

If we think \( \Theta_t \) as the “state” and \( H_t \) as the “observation” matrix, then a direct application of the Kalman algorithm to the above equations gives the recursion

\[ \hat{\Theta}_t = F_{t-1} \hat{\Theta}_{t-1} + K_t (X_t - H_t F_{t-1} \hat{\Theta}_{t-1}) \]
where $K_t$ is the Kalman “gain” matrix given by

$$K_t = \Phi_t (H_t)(H_t \Phi_t (H_t)^T + \sigma_e^2)^{-1}$$

$$\Phi_t = F_{t-1} C_{t-1} (F_{t-1})^T + \Sigma_W$$

$$C_t = \Phi_t - K_t (H_t \Phi_t (H_t)^T + \sigma_e^2)(K_t)^T$$
The initial states are obtained by fitting an AR model for an initial Stretch of data.
